
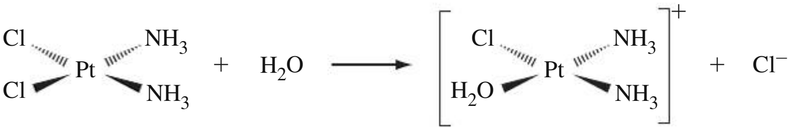
It might seem strange that only one isomer (the *cis* isomer) is obtained. One way to rationalize why this happens is to consider the ligands in $[Pt(NH_3)I_3]^-$ in terms of their tendencies to direct an incoming ligand toward the *trans* position. Empirical studies indicate that NH_3 is a weaker *trans* director than is I^-, and so the second NH_3 molecule is preferentially directed to a position that is *trans* to I^-, rather than being directed to a position that is *trans* to NH_3. As pointed out in the margin note, Cl^- is a weaker *trans* director than is I^-, so treatment of $K_2[PtCl_4]$ with NH_3 will give a lower yield of the *cis* isomer of $Pt(NH_3)_2Cl_2$. Consequently, the conversion of $K_2[PtCl_4]$ to $K_2[PtI_4]$ is an important step in the synthesis.

◀ Empirically, certain ligands are found to have a greater tendency than others to direct an incoming ligand toward a *trans* position. For the monodentate ligands we have encountered, the approximate ordering from strongest *trans* directors to weakest *trans* directors is $CN^-, CO > NO_2^-, I^- > Br^- > Cl^- > NH_3 > OH^- > H_2O$.

The remaining steps in preparing cisplatin are as follows. When *cis*-$[PtI_2(NH_3)_2]$ is treated with $AgNO_3$, insoluble AgI precipitates, leaving behind a solution of *cis*-$[Pt(OH_2)_2(NH_3)_2]^{2+}$. Finally, treatment with KCl gives *cis*-$[PtCl_2(NH_3)_2]$ as a yellow precipitate.

Let's now consider the essential features of the anticancer activity of cisplatin. Cisplatin enters cancer cells mainly by diffusion. Once inside the cell, one of the chloride ions in cisplatin is replaced by a water molecule.



Cisplatin

The anticancer activity of cisplatin is associated with the binding of $[Pt(NH_3)_2(Cl)(H_2O)]^+$ to a cellular DNA molecule. (We will discuss DNA in more detail in Chapter 28.) When $[Pt(NH_3)_2(Cl)(H_2O)]^+$ binds to a DNA molecule, structural deformations occur in the DNA molecule and these deformations, if not repaired by proteins in the cell, lead ultimately to cell death.

It may seem surprising that the *cis* and *trans* isomers of $Pt(NH_3)_2Cl_2$ exhibit a dramatic difference in anticancer activity, given their structural similarities. Overall, the *trans* isomer (transplatin) is more reactive and potentially more potent than cisplatin but the higher reactivity leads ultimately to lower anticancer activity. Because of its increased reactivity, transplatin can undergo many side reactions before it reaches its target; thus, transplatin is less effective in killing cancer cells.

The discovery of the anticancer activity of cisplatin was nothing less than monumental. To date, thousands of platinum-containing compounds have been investigated as potential chemotherapy drugs. Worldwide annual sales of platinum-based anticancer drugs are currently in excess of $2 billion.

Hydrates

When a compound is crystallized from an aqueous solution of its ions, the crystals obtained are often hydrated. As originally described in Chapter 3, a hydrate is a substance that has a fixed number of water molecules associated with each formula unit. In some cases, the water molecules are ligands bonded directly to a metal ion. The coordination compound $[Co(H_2O)_6](ClO_4)_2$ may be represented as the hexahydrate, $Co(ClO_4)_2 \cdot 6\,H_2O$. In the hydrate $CuSO_4 \cdot 5\,H_2O$, four H_2O molecules are associated with copper in the complex ion $[Cu(H_2O)_4]^{2+}$, and the fifth with the $SO_4{}^{2-}$ anion by hydrogen bonding. Another possibility for hydrate formation is that the water molecules may be incorporated into definite positions in the solid crystal but not associated with any particular cations or anions, as in $BaCl_2 \cdot 2\,H_2O$. This is called *lattice water*. Finally, part of the water may be coordinated to an ion and part of it may be lattice water, as appears to be the case with alums, such as $KAl(SO_4)_2 \cdot 12\,H_2O$.

Stabilization of Oxidation States

The standard electrode potential for the reduction of Co(III) to Co(II) is

$$Co^{3+}(aq) + e^- \longrightarrow Co^{2+}(aq) \quad E° = +1.82\ V$$

This large positive value suggests that $Co^{3+}(aq)$ is a strong oxidizing agent, strong enough to oxidize water to $O_2(g)$.

$$4\,Co^{3+}(aq) + 2\,H_2O(l) \longrightarrow 4\,Co^{2+}(aq) + 4\,H^+(aq) + O_2(g) \quad E°_{cell} = +0.59\ V \tag{24.12}$$

Yet one of the complex ions featured in this chapter has been $[Co(NH_3)_6]^{3+}$. This ion is stable in water solution, even though it contains cobalt in the +3 oxidation state. Reaction (24.12) will not occur if the concentration of Co^{3+} is sufficiently low and $[Co^{3+}]$ is kept very low because of the great stability of the complex ion.

$$Co^{3+}(aq) + 6\,NH_3(aq) \rightleftharpoons [Co(NH_3)_6]^{3+}(aq) \qquad \beta_6 = K_f = 4.5 \times 10^{33}$$

In fact, the concentration of free Co^{3+} is so low that for the half-reaction

$$[Co(NH_3)_6]^{3+} + e^- \longrightarrow [Co(NH_3)_6]^{2+}$$

$E°$ is only +0.10 V. As a consequence, not only is $[Co(NH_3)_6]^{3+}$ stable but also $[Co(NH_3)_6]^{2+}$ is rather easily oxidized to the Co(III) complex.

The ability of strong electron-pair donors (strong Lewis bases) to stabilize high oxidation states in the way that NH_3 does in Co(III) complexes and O^{2-} in Mn(VII) complexes (such as $MnO_4{}^-$) affords a means of attaining certain oxidation states that might otherwise be difficult or impossible to attain.

Photography: Fixing a Photographic Film

A black-and-white photographic film is an emulsion of a finely divided silver halide (typically AgBr) coated on a strip of polymer, such as a modified cellulose. In the *exposure* step, the film is exposed to light and some of the tiny granules of AgBr(s) absorb photons. The photons promote the oxidation of Br^- to Br and the reduction of Ag^+ to Ag. The Ag and Br atoms remain in the crystalline lattice of AgBr(s) as "defects," in numbers that depend on the intensity of the light absorbed: The brighter the light, the more Ag atoms. Because the actual number of Ag atoms produced in the exposure is not large, the silver is invisible to the eye. The pattern of distribution of the Ag atoms, however, creates a *latent* image of the object photographed. To obtain a visible image, the film is developed.

In the *developing* step, the exposed film is placed in a solution of a mild reducing agent such as hydroquinone, $C_6H_4(OH)_2$. An oxidation–reduction reaction occurs in which Ag^+ ions are reduced to Ag and the hydroquinone is oxidized. The action of the developer is such that reduction of Ag^+ to Ag occurs just in those granules of AgBr(s) that contain Ag atoms of the latent image. As a result, the number of Ag atoms in the film is greatly increased, and the latent image becomes visible. Bright regions of the photographed object appear as dark regions in the photographic image. At this stage, the film is a photographic *negative*. This negative cannot be exposed to light, however, because reduction of Ag^+ to Ag could still occur in the previously unexposed granules of AgBr(s). The negative must be fixed.

The *fixing* step requires that the black metallic silver of the negative remain on the film and the unexposed AgBr(s) be removed. A common fixer is an aqueous solution of sodium thiosulfate (also known as sodium hyposulfite or hypo). Because the complex ion $[Ag(S_2O_3)_2]^{3-}$ has a large formation constant, the following reaction is driven to completion—the AgBr(s) dissolves.

$$\mathrm{AgBr(s)} + 2\,\mathrm{S_2O_3}^{2-}\mathrm{(aq)} \longrightarrow [\mathrm{Ag(S_2O_3)_2}]^{3-}\mathrm{(aq)} + \mathrm{Br^-(aq)} \qquad \textbf{(24.13)}$$

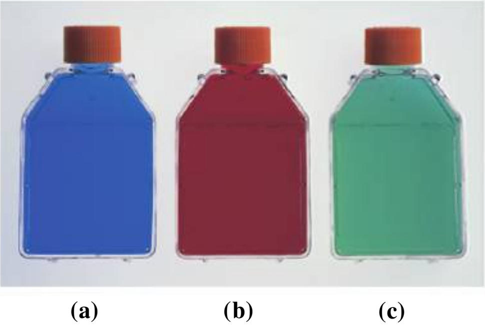
Once the negative has been fixed, it is used to produce a *positive* image, the final photograph. This is done by projecting light through the negative onto a piece of photographic paper. Regions of the negative that are dark transmit little light to the photographic paper and will appear light when the photographic paper is subsequently developed and fixed. Conversely, light areas of the negative will appear dark in the final print. In this way, the areas of light and dark in the final print are the same as in the photographed object.

Qualitative Analysis

In discussing qualitative cation analysis in Section 18-9 (page 805), we showed how the group 1 precipitate—AgCl(s), $PbCl_2(s)$, or $Hg_2Cl_2(s)$—is separated by taking advantage of the stable complex ion formed by $Ag^+(aq)$ and $NH_3(aq)$.

$$\mathrm{AgCl(s)} + 2\,\mathrm{NH_3(aq)} \longrightarrow [\mathrm{Ag(NH_3)_2}]^{+}\mathrm{(aq)} + \mathrm{Cl^-(aq)}$$

The qualitative analysis scheme abounds in other examples of complexion formation. For example, at a point in the procedure for cation group 3, a test is needed for Co^{2+}. In the presence of SCN^- ion, Co^{2+} forms a blue thiocyanato complex ion, $[Co(SCN)_4]^{2-}$ (Fig. 24-22a). A problem develops, however, if even a trace amount of Fe^{3+} is present in the solution. Fe^{3+} reacts with SCN^- to produce $[FeSCN(H_2O)_5]^{2+}$, a strongly colored, blood-red complex ion (Fig. 24-22b.) Fortunately, this complication can be resolved by treating a solution containing both Co^{2+} and Fe^{3+} with an excess of F^-. The Fe^{3+} is converted to the extremely stable, pale yellow $[FeF_6]^{3-}$. The complex ion $[CoF_4]^{2-}$, being much less stable than $[Co(SCN)_4]^{2-}$, does not form. As a result, the $[Co(SCN)_4]^{2-}(aq)$ can be detected via the blue-green solution color (Fig. 24-22c).



▶ FIGURE 24-22
Qualitative tests for Co^{2+} and Fe^{3+}

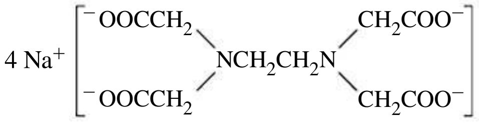
(c) Mixture of $[FeF_6]^{3-}$ and $[Co(SCN)_4]^{2-}$.

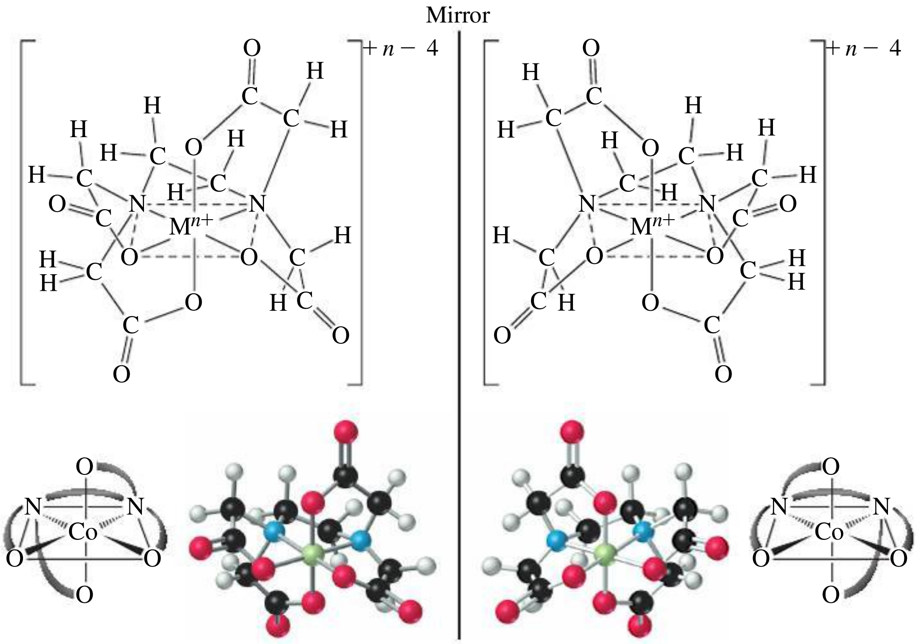
Sequestering Metal Ions

Metal ions can act as unintended catalysts in promoting undesirable chemical reactions in a manufacturing process, or they may alter the properties of the material being manufactured. Thus, for many industrial purposes, it is imperative to remove mineral impurities from water. Often these impurities, such as Cu^{2+}, are present only in trace amounts, and precipitation of metal ions is feasible only if K_{sp} for the precipitate is very small. An alternative is to treat the water with a chelating agent. This reduces the free cation concentrations to the point at which the cations can no longer enter into objectionable reactions. The cations are said to be *sequestered*. Among the chelating agents widely employed are the salts of *ethylenediaminetetraacetic acid* (H_4EDTA), usually as the sodium salt.



$$4\,Na^+\left[\begin{matrix} {}^-OOCCH_2 & & CH_2COO^- \\ & NCH_2CH_2N & \\ {}^-OOCCH_2 & & CH_2COO^- \end{matrix}\right]$$

A representative complex ion formed by a metal ion, M^{n+}, with the hexadentate $EDTA^{4-}$ anion is depicted in Figure 24-23. The high stability of such complexes can be attributed to the presence of five, five-member chelate rings.



▶ FIGURE 24-23
Structure of a metal–EDTA complex
The central metal ion M^{n+} (pale green) can be Ca^{2+}, Mg^{2+}, Fe^{2+}, Fe^{3+}, and so on. The ligand is $EDTA^{4-}$, and the net charge on the complex is $+n-4$. Structural diagrams and ball-and-stick models are shown for the two optical isomers of an $[MEDTA]^{n-4}$ complex.

In the presence of $EDTA^{4-}(aq)$, Ca^{2+}, Mg^{2+}, and Fe^{3+} in hard water are unable to form boiler scale or to precipitate as insoluble soaps. The cations are sequestered in the complex ions: $[Ca(EDTA)]^{2-}$, $[Mg(EDTA)]^{2-}$, and $[Fe(EDTA)]^{-}$, having K_f values of 4.0×10^{10}, 4.0×10^{8}, and 1.7×10^{24}, respectively.

Chelation with EDTA can be used in treating some cases of metal poisoning. If a person with lead poisoning is fed $[Ca(EDTA)]^{2-}$, the following exchange occurs because $[Pb(EDTA)]^{2-}$ ($K_f = 2 \times 10^{18}$) is even more stable than $[Ca(EDTA)]^{2-}$ ($K_f = 4 \times 10^{10}$).

$$Pb^{2+} + [Ca(EDTA)]^{2-} \longrightarrow [Pb(EDTA)]^{2-} + Ca^{2+}$$

The body excretes the lead complex, and the Ca^{2+} remains as a nutrient. A similar method can be used to rid the body of radioactive isotopes, as in the treatment of plutonium poisoning.

Some plant fertilizers contain EDTA chelates of metals such as Cu^{2+} as a soluble form of the metal ion for the plant to use. Metal ions can catalyze reactions that cause mayonnaise and salad dressings to spoil, and the addition of EDTA reduces the concentration of metal ions by chelation.

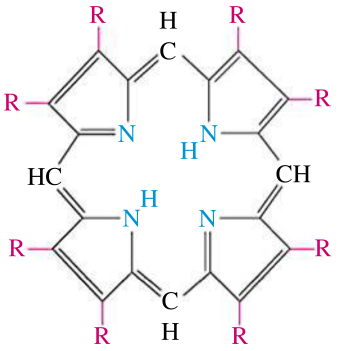
Biological Applications: Porphyrins

The structure in Figure 24-24 is commonly found in both plant and animal matter. If the eight R groups are all H atoms, the molecule is called *porphin*. The central N atoms can give up their H atoms, and a metal atom can coordinate simultaneously with all four N atoms. The porphin is a tetradentate ligand for the central metal, and the metal–porphin complex is called a *porphyrin*. Specific porphyrins differ in their central metals and in the R groups on the porphin rings.

In *photosynthesis*, carbon dioxide and water, in the presence of inorganic salts, a catalytic agent called *chlorophyll*, and sunlight, combine to form carbohydrates.

$$n\,CO_2 + n\,H_2O \xrightarrow[\text{chlorophyll}]{\text{sunlight}} \underset{\text{carbohydrates}}{(CH_2O)_n} + n\,O_2 \qquad \textbf{(24.14)}$$



▲ FIGURE 24-24
The porphyrin structure

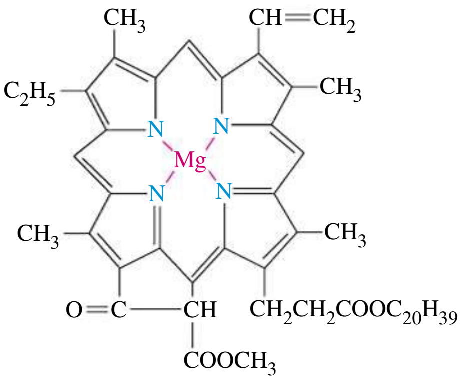
Carbohydrates are the main structural materials of plants. Chlorophyll is a green pigment that absorbs sunlight and directs the storage of this energy into the chemical bonds of the carbohydrates. The structure of one type of chlorophyll is shown in Figure 24-25; it is a porphyrin. The central metal ion is Mg^{2+}.

Green is the complementary color of magenta—a purplish red—so we should expect chlorophyll to absorb light in the red region of the spectrum (about 670–680 nm). This suggests that green plants should grow more readily in red light than in light of other colors, and some experimental evidence indicates that this is the case. For example, the maximum rate of formation of $O_2(g)$ by reaction (24.14) occurs with red light.

In Chapter 28, we will consider another porphyrin structure that is essential to life—hemoglobin.

KEEP IN MIND

magnesium is not a transition metal.



◀ FIGURE 24-25
Structure of chlorophyll *a*

Transition metal ions are responsible for the brilliant colors in many gemstones. For a discussion of the ions responsible for the colors of rubies and emeralds, and the mechanisms that allow these gemstones to maintain their colors indefinitely, go to the Focus On feature for Chapter 24, Colors in Gemstones, on the MasteringChemistry site.

Summary

24-1 Werner's Theory of Coordination Compounds: An Overview—Many metal atoms or ions, particularly among the transition elements, have the ability to bond with **ligands** (electron-pair donors) to form a **complex**, a species in which there are coordinate covalent bonds between ligands and metal centers. The number of electron pairs donated to the central metal atom or ion by the ligands is the **coordination number**. A compound having one or more complexes as a constituent is called a **coordination compound**.

24-2 Ligands—A ligand that attaches to a central metal atom or ion by donating a single electron pair is said to be **monodentate**. A **bidentate** ligand binds to the central metal atom or ion with two pairs of electrons (Fig. 24-3). **Polydentate** ligands are able to attach simultaneously to two or more positions at the metal center. This multiple attachment produces complexes with five- or six-member rings of atoms—**chelates**. A polydentate ligand is also referred to as a **chelating agent**.

24-3 Nomenclature—The name of a complex conveys information about the number and kinds of ligands; the oxidation state of the metal center; and whether the complex is a neutral species, a cation, or an anion.

24-4 Isomerism—The positions at which ligands are attached to the metal center are not always equivalent, and as a consequence isomerism occurs in coordination complexes. **Structural isomers** differ in what ligands are attached to the metal ion and through which atoms, one example being linkage isomerism (Fig. 24-4). In **geometric isomerism**, different structures with different properties result, depending on where the attachment of ligands occurs. In coordination complexes in which there are two ligands of one type and the remainder of another type, the *cis* isomer has the two identical ligands on the same side of a square in a planar structure (Fig. 24-5) or the same edge of an octahedral structure (Fig. 24-6). The ***trans*** isomer has the two ligands on opposite corners of a square (Fig. 24-5) or diametrically opposed in an octahedral structure (Fig. 24-6). **Optical isomers** differ by being nonsuperimposable mirror images of each other (Fig. 24-8). The two isomers so related are called **enantiomers** and they are said to be **chiral**. Optical isomerism and geometrical isomerism are forms of **stereoisomerism**, that is, isomerism based on the way ligands occupy the three-dimensional space around the metal center.

24-5 Bonding in Complex Ions: Crystal Field Theory—**Crystal field theory** is a bonding theory useful in explaining the magnetic properties and characteristic colors of complex ions (Fig. 24-11). This theory emphasizes the splitting of the *d* energy level of the central metal ion as a result of repulsions between *d*-orbital electrons of the central ion and electrons of the ligands (Fig. 24-12). Whether or not electrons are accommodated in the upper *d* orbitals depends on whether the crystal field splitting, Δ, is greater than the **pairing energy** (P). In d^n complexes, where $4 \leq n \leq 7$, **low spin** complexes occur when $P > \Delta$, and **high spin** complexes occur when $P < \Delta$. A prediction of the magnitude of *d*-level splitting produced by a ligand can be made via the ranking known as the **spectrochemical series.**

24-6 Magnetic Properties of Coordination Compounds and Crystal Field Theory—The magnetic properties of coordination compounds—whether diamagnetic or paramagnetic, and to what degree—can be assessed by measuring the change in weight of the substance when placed in a magnetic field (Fig. 24-15).

24-7 Color and the Colors of Complexes—The colors displayed by coordination complexes (Fig. 24-18) arise from the absorption of certain wavelength components of white light as an electron is excited from a lower energy *d* orbital to a higher energy *d* orbital in a crystal field. The transmitted light is deficient in the absorbed wavelengths and hence of a different color. The relationship of **primary, secondary**, and **complementary colors** is described and presented visually in Figure 24-16.

24-8 Aspects of Complex-Ion Equilibria—Formation of a coordination complex can be viewed as a stepwise equilibrium process in which other ligands displace H_2O molecules from aqua complex ions. The stepwise constants can be combined into an overall formation constant for the complex ion, K_f. When a chelating agent binds to a metal ion, an increased stability is observed because of the entropy changes produced when the chelating agent displaces water molecules from binding sites in the coordination sphere. This greater stability achieved is called the **chelation (chelate) effect**.

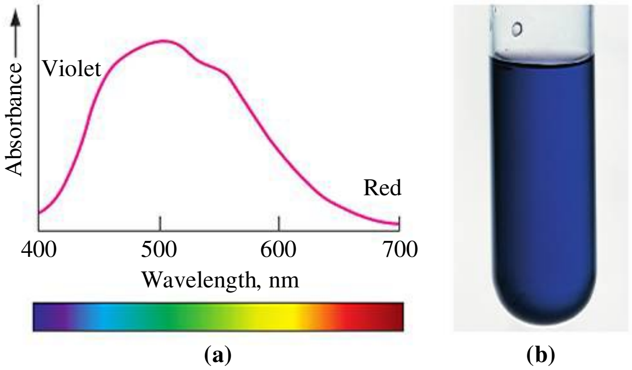
24-9 Acid–Base Reactions of Complex Ions—The ability of ligand water molecules to ionize causes some aqua complexes to exhibit acidic properties and helps explain amphoterism.

24-10 Some Kinetic Considerations—Also important in determining properties of a complex ion is the rate at which the ion exchanges ligands between its coordination sphere and the solution. Exchange is rapid in a **labile** complex and slow in an **inert** complex.

24-11 Applications of Coordination Chemistry—Complex-ion formation can be used to stabilize certain oxidation states, such as Co(III). Other applications include dissolving precipitates, such as AgCl by $NH_3(aq)$ in the qualitative analysis scheme and AgBr by $Na_2S_2O_3(aq)$ in the photographic process, and sequestering ions by chelation, as with EDTA.

Integrative Example

Absorbance is a measure of the proportion of monochromatic (single-color) light that is absorbed as the light passes through a solution. An *absorption spectrum* is a graph of absorbance as a function of wavelength. High absorbances correspond to large proportions of the light entering a solution being absorbed. Low absorbances signify that large proportions of the light are transmitted. The absorption spectrum of $[Ti(H_2O)_6]^{3+}(aq)$ is shown in Figure 24-26(a).



◀ FIGURE 24-26
The color of $[Ti(H_2O)_6]^{3+}(aq)$
(a) The absorption spectrum of $[Ti(H_2O)_6]^{3+}(aq)$.
(b) A solution containing $[Ti(H_2O)_6]^{3+}(aq)$.

(a) Describe the color of light that $[Ti(H_2O)_6]^{3+}(aq)$ absorbs most strongly, and the color of the solution. **(b)** Describe the electron transition responsible for the absorption peak, and determine the energy associated with this absorption.

Analyze

The highest absorbances in the spectrum shown in Fig. 24-26(a)) come at about 500 nm. We use the electromagnetic spectrum in Figure 8-3 to determine the color of the absorbed light. We determine that the electron configuration of Ti^{3+}, the central ion in the complex ion, is $[Ar]3d^1$. In the ground state, the $3d$ electron is in one of the three degenerate lower levels in the d-orbital splitting diagram for an octahedral complex (Fig. 24-12).

Solve

(a) The electromagnetic spectrum in Figure 8-3 indicates that the absorbed light should be dark green. Fig. 24-16(b) indicates that, in subtractive color mixing, the complementary color of green is magenta. Thus the color of the transmitted light (and hence the observed color of the solution) is a blend of red and blue.

(b) The quantity of energy we seek is that corresponding to electromagnetic radiation at the peak of the absorption spectrum: 500 nm. First we can establish the frequency of this light from $c = \nu \times \lambda$.

$$\nu = \frac{c}{\lambda} = \frac{2.998 \times 10^8\ \text{m s}^{-1}}{500 \times 10^{-9}\ \text{m}} = 6.00 \times 10^{14}\ \text{s}^{-1}$$

Then, we use Planck's equation to determine E:

$$E = h\nu = (6.626 \times 10^{-34}\ \text{J s}) \times (6.00 \times 10^{14}\ \text{s}^{-1}) = 3.98 \times 10^{-19}\ \text{J}$$

This is the energy per photon. If we want the energy on a per-mole basis, we can write

$$E = (3.98 \times 10^{-19}\ \text{J photon}^{-1}) \times (6.022 \times 10^{23}\ \text{photon mol}^{-1}) \times \frac{1\ \text{kJ}}{1000\ \text{J}}$$
$$= 240\ \text{kJ mol}^{-1}$$

Assess

Using ideas of subtractive color mixing, we ascertained the wavelength components of white light that the complex cation absorbs. The broadness of the absorption band is due to vibrations in the metal to oxygen bonds. By using the maximum of the absorption curve, we calculated the most probable energy of the absorbed photons.

PRACTICE EXAMPLE A: The compound $Co(en)_2(NO_2)_2Cl$ has been prepared in a number of isomeric forms. One form undergoes no reaction with either $AgNO_3$ or en and is optically inactive. A second form reacts with $AgNO_3$ to form a white precipitate, does not react readily with en, and is optically inactive. A third form is optically active and reacts both with en and $AgNO_3$. Assuming a coordination number of 6 for the cobalt ion, identify each of the three isomeric forms by name, and sketch each of the structures.

PRACTICE EXAMPLE B: A compound is analyzed and found to contain 46.2% Pt, 33.6% Cl, 16.6% N, and 3.6% H. The freezing point of a 0.1 M aqueous solution of the compound is −0.74 °C. What is the structural formula of the compound? What possible isomeric forms are there for this compound?

Exercises

Nomenclature

1. Write the formula and name of
   (a) a complex ion having Cr^{3+} as the central ion and two NH_3 molecules and four Cl^- ions as ligands
   (b) a complex ion of iron(III) having a coordination number of 6 and CN^- as ligands
   (c) a coordination compound comprising two types of complex ions: one a complex of Cr(III) with ethylenediamine (en), having a coordination number of 6; the other, a complex of Ni(II) with CN^-, having a coordination number of 4
2. What are the coordination number and the oxidation state of the central metal ion in each of the following complexes? Name each complex.
   (a) $[Co(NH_3)_6]^{2+}$
   (b) $[AlF_6]^{3-}$
   (c) $[Cu(CN)_4]^{2-}$
   (d) $[CrBr_2(NH_3)_4]^+$
   (e) $[Co(ox)_3]^{4-}$
   (f) $[Ag(S_2O_3)_2]^{3-}$
3. Supply acceptable names for the following.
   (a) $[Co(OH)(H_2O)_4(NH_3)]^{2+}$
   (b) $[Co(ONO)_3(NH_3)_3]$
   (c) $[Pt(H_2O)_4][PtCl_6]$
   (d) $[Fe(ox)_2(H_2O)_2]^-$
   (e) $Ag_2[HgI_4]$
4. Write appropriate formulas for the following.
   (a) potassium hexacyanoferrate(III)
   (b) bis(ethylenediamine)copper(II) ion
   (c) pentaaquahydroxoaluminum(III) chloride
   (d) amminechlorobis(ethylenediamine)chromium(III) sulfate
   (e) tris(ethylenediamine)iron(III) hexacyanoferrate(II)

Bonding and Structure in Complex Ions

5. Draw Lewis structures for the following ligands: **(a)** H_2O; **(b)** CH_3NH_2; **(c)** ONO^-; **(d)** SCN^-.
6. Draw Lewis structures for the following ligands: **(a)** hydroxo; **(b)** sulfato; **(c)** oxalato; **(d)** thiocyanato-*N*-.
7. Draw a plausible structure to represent:
   (a) $[PtCl_4]^{2-}$
   (b) *fac*-$[Co(H_2O)_3(NH_3)_3]^{2+}$
   (c) $[CrCl(H_2O)_5]^{2+}$
8. Draw plausible structures of the following chelate complexes.
   (a) $[Pt(ox)_2]^{2-}$
   (b) $[Cr(ox)_3]^{3-}$
   (c) $[Fe(EDTA)]^{2-}$
9. Draw plausible structures corresponding to each of the following names.
   (a) pentamminesulfatochromium(III) ion
   (b) trioxalatocobaltate(III) ion
   (c) triamminedichloronitrito-*O*-cobalt(III)
10. Draw plausible structures corresponding to each of the following names.
    (a) pentamminenitrito-*N*-cobalt(III) ion
    (b) ethylenediaminedithiocyanato-*S*-copper(II)
    (c) hexaaquanickel(II) ion

Isomerism

11. Which of these general structures for a complex ion would you expect to exhibit *cis* and *trans* isomerism? Explain.
    (a) tetrahedral
    (b) square-planar
    (c) linear

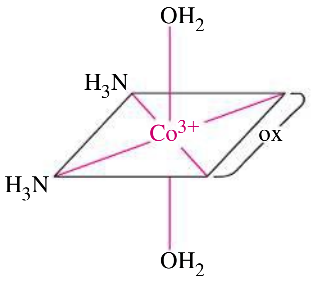
12. Which of these octahedral complexes would you expect to exhibit *geometric* isomerism? Explain.
    (a) $[CrOH(NH_3)_5]^{2+}$
    (b) $[CrCl_2(H_2O)(NH_3)_3]^{+}$
    (c) $[CrCl_2(en)_2]^{+}$
    (d) $[CrCl_4(en)]^{-}$
    (e) $[Cr(en)_3]^{3+}$

13. If A, B, C, and D are four different ligands,
    (a) how many geometric isomers will be found for square-planar $[PtABCD]^{2+}$?
    (b) Will tetrahedral $[ZnABCD]^{2+}$ display optical isomerism?

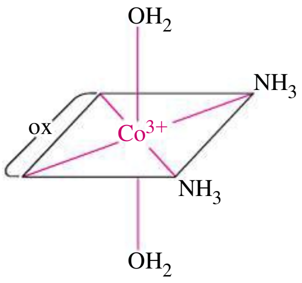
14. Write the names and formulas of three coordination isomers of $[Co(en)_3][Cr(ox)_3]$.

15. Draw a structure for *cis*-dichlorobis(ethylenediamine)cobalt(III) ion. Is this ion chiral? Is the *trans* isomer chiral? Explain.

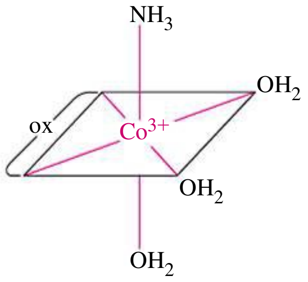
16. The structures of four complex ions are given. Each has Co^{3+} as the central ion. The ligands are H_2O, NH_3, and oxalate ion, $C_2O_4^{2-}$. Determine which, *if any*, of these complex ions are isomers (geometric or optical); which, *if any*, are identical (that is, have identical structures); and which, *if any*, are distinctly different.



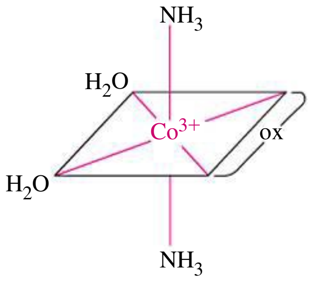
(a)



(b)



(c)



(d)

Crystal Field Theory

17. Describe how the crystal field theory explains the fact that so many transition metal compounds are colored.

18. Cyano complexes of transition metal ions (such as Fe^{2+} and Cu^{2+}) are often yellow, whereas aqua complexes are often green or blue. Explain the basis for this difference in color.

19. If the ion Co^{2+} is linked with strong-field ligands to produce an octahedral complex, the complex has *one* unpaired electron. If Co^{2+} is linked with weak-field ligands, the complex has *three* unpaired electrons. How do you account for this difference?

20. In contrast to the case of Co^{2+} considered in Exercise 19, no matter what ligand is linked to Ni^{2+} to form an octahedral complex, the complex always has *two* unpaired electrons. Explain this fact.

21. Predict:
    (a) which of the complex ions, $[MoCl_6]^{3-}$ and $[Co(en)_3]^{3+}$, is diamagnetic and which is paramagnetic;
    (b) the number of unpaired electrons expected for the tetrahedral complex ion $[CoCl_4]^{2-}$.

22. Predict:
    (a) whether the square-planar complex ion $[Cu(py)_4]^{2+}$ is diamagnetic or paramagnetic
    (b) whether octahedral $[Mn(CN)_6]^{3-}$ or tetrahedral $[FeCl_4]^{-}$ has the greater number of unpaired electrons.

23. In Example 24-5, we chose between a tetrahedral and a square-planar structure for $[Ni(CN)_4]^{2-}$ based on magnetic properties. Could we similarly use magnetic properties to establish whether the ammine complex of Ni(II) is octahedral $[Ni(NH_3)_6]^{2+}$ or tetrahedral $[Ni(NH_3)_4]^{2+}$? Explain.

24. In both $[Fe(H_2O)_6]^{2+}$ and $[Fe(CN)_6]^{4-}$ ions, the iron is present as Fe(II); however, $[Fe(H_2O)_6]^{2+}$ is paramagnetic, whereas $[Fe(CN)_6]^{4-}$ is diamagnetic. Explain this difference.

Complex-Ion Equilibria

25. Write equations to represent the following observations.
    (a) A mixture of $Mg(OH)_2(s)$ and $Zn(OH)_2(s)$ is treated with $NH_3(aq)$. The $Zn(OH)_2$ dissolves, but the $Mg(OH)_2(s)$ is left behind.
    (b) When NaOH(aq) is added to $CuSO_4(aq)$, a pale blue precipitate forms. If $NH_3(aq)$ is added, the precipitate redissolves, producing a solution with an intense deep blue color. If this deep blue solution is made acidic with $HNO_3(aq)$, the color is converted back to pale blue.

26. Write equations to represent the following observations.
    (a) A quantity of $CuCl_2(s)$ is dissolved in concentrated HCl(aq) and produces a yellow solution. The solution is diluted to twice its volume with water and assumes a green color. On dilution to ten times its original volume, the solution becomes pale blue.

(b) When chromium metal is dissolved in HCl(aq), a blue solution is produced that quickly turns green. Later the green solution becomes blue-green and then violet.

27. Which of the following complex ions would you expect to have the largest overall K_f, and why? $[Co(NH_3)_6]^{3+}$, $[Co(en)_3]^{3+}$, $[Co(H_2O)_6]^{3+}$, $[Co(H_2O)_4(en)]^{3+}$.

28. Use data from Table 24.6 to determine values of **(a)** β_4 for the formation of $[Zn(NH_3)_4]^{2+}$; **(b)** β_4 for the formation of $[Ni(H_2O)_2(NH_3)_4]^{2+}$.

29. Write a series of equations to show the stepwise displacement of H_2O ligands in $[Fe(H_2O)_6]^{3+}$ by ethylenediamine, for which $\log K_1 = 4.34$, $\log K_2 = 3.31$, and $\log K_3 = 2.05$. What is the overall formation constant, $\beta_3 = K_f$, for $[Fe(en)_3]^{3+}$?

30. A tabulation of formation constant data lists the following log K values for the formation of $[CuCl_4]^{2-}$: $\log K_1 = 2.80$, $\log K_2 = 1.60$, $\log K_3 = 0.49$, and $\log K_4 = 0.73$. What is the overall formation constant $\beta_4 = K_f$ for $[CuCl_4]^{2-}$?

31. Explain the following observations in terms of complex-ion formation.
    (a) $Al(OH)_3(s)$ is soluble in NaOH(aq) but insoluble in $NH_3(aq)$.
    (b) $ZnCO_3(s)$ is soluble in $NH_3(aq)$, but ZnS(s) is not.
    (c) The molar solubility of AgCl in pure water is about 1×10^{-5} M; in 0.04 M NaCl(aq), it is about 2×10^{-6} M; but in 1 M NaCl(aq), it is about 8×10^{-5} M.

32. Explain the following observations in terms of complex-ion formation.
    (a) $CoCl_3$ is unstable in aqueous solution, being reduced to $CoCl_2$ and liberating $O_2(g)$. Yet, $[Co(NH_3)_6]Cl_3$ can be easily maintained in aqueous solution.
    (b) AgI is insoluble in water and in dilute $NH_3(aq)$, but AgI will dissolve in an aqueous solution of sodium thiosulfate.

Acid–Base Properties

33. Which of the following would you expect to react as a Brønsted–Lowry acid: $[Cu(NH_3)_4]^{2+}$, $[FeCl_4]^-$, $[Al(H_2O)_6]^{3+}$, or $[Zn(OH)_4]^{2-}$? Why?

34. Write simple chemical equations to show how the complex ion $[CrOH(H_2O)_5]^{2+}$ acts as **(a)** an acid; **(b)** a base.

Applications

35. From data in Chapter 18,
    (a) Derive an equilibrium constant for reaction (24.13), and explain why this reaction (the fixing of photographic film) is expected to go essentially to completion.
    (b) Explain why $NH_3(aq)$ cannot be used in the fixing of photographic film.

36. Show that the oxidation of $[Co(NH_3)_6]^{2+}$ to $[Co(NH_3)_6]^{3+}$ referred to on page 1098 should occur spontaneously in alkaline solution with H_2O_2 as an oxidizing agent.

37. Explain why $K_2[PtCl_4]$ is first converted to $K_2[PtI_4]$ in the synthesis of the anticancer drug cisplatin, *cis*-$Pt(NH_3)_2Cl_2$.

38. Draw dashed and solid wedge diagrams of transplatin, *trans*-$Pt(NH_3)_2Cl_2$, and cisplatin, *cis*-$Pt(NH_3)_2Cl_2$. Then, explain how transplatin can be more reactive yet less effective at killing cancer cells than is cisplatin.

Integrative and Advanced Exercises

39. From each of the following names, you should be able to deduce the formula of the complex ion or coordination compound intended. Yet, these are not the best systematic names that can be written. Replace each name with one that is more acceptable: **(a)** cupric tetraammine ion; **(b)** dichlorotetraammine cobaltic chloride; **(c)** platinic(IV) hexachloride ion; **(d)** disodium copper tetrachloride; **(e)** dipotassium antimony(III) pentachloride.

40. Magnus's green salt has the empirical formula $PtCl_2 \cdot 2\,NH_3$. It is a coordination compound consisting of both complex cations and complex anions. Write the probable formula of this coordination compound according to Werner's theory, and assign it a systematic name.

41. How many isomers are there of the complex ion $[CoCl_2(en)(NH_3)_2]^+$? Sketch their structures.

42. Explain the following observations through a series of equations. The green solid $CrCl_3 \cdot 6\,H_2O$ dissolves in water to form a green solution. The solution slowly turns blue-green; after a day or two, the solution is violet. When the violet solution evaporates to dryness, a green solid remains.

43. The *cis* and *trans* isomers of $[CoCl_2(en)_2]^+$ can be distinguished via a displacement reaction with oxalate ion. What difference in reactivity toward oxalate ion would you expect between the *cis* and *trans* isomers? Explain.

44. Write half-equations and an overall equation to represent the oxidation of tetraammineplatinum(II) ion to *trans*-tetraamminedichloroplatinum(IV) ion by Cl_2. Then make sketches of the two complex ions.

45. We learned in Chapter 16 that for polyprotic acids, ionization constants for successive ionization steps decrease rapidly. That is, $K_{a_1} \gg K_{a_2} \gg K_{a_3}$. The ionization constants for the first two steps in the ionization of $[Fe(H_2O)_6]^{3+}$ (reactions 24.10 and 24.11) are more nearly equal in magnitude. Why does this multistep ionization seem not to follow the pattern for polyprotic acids?

46. Following are the names of five coordination compounds containing complexes with platinum(II) as the central metal ion and ammonia molecules and/or chloride ions as ligands: **(a)** potassium amminetrichloroplatinate(II), **(b)** diamminedichloroplatinum(II), **(c)** triamminechloroplatinum(II) chloride, **(d)** tetraammineplatinum(II) chloride, **(e)** potassium tetrachloroplatinate(II). Make a rough sketch of the expected graph when electric conductivity is plotted as a function of the chlorine content of the compounds. [*Hint:* Your graph should be based on five points, but no quantitative data are given.]

47. For a solution that is 0.100 M in $[Fe(H_2O)_6]^{3+}$,

(a) assuming that ionization of the aqua complex ion proceeds only through the first step, equation (24.10), calculate the pH of the solution.

(b) Calculate $[[FeOH(H_2O)_5]^{2+}]$ if the solution is also 0.100 M $HClO_4$. (ClO_4^- does not complex with Fe^{3+}.)

(c) Can the pH of the solution be maintained so that $[[FeOH(H_2O)_5]^{2+}]$ does not exceed 1×10^{-6} M? Explain.

48. A solution that is 0.010 M in Pb^{2+} is also made to be 0.20 M in a salt of EDTA (that is, having a concentration of the $EDTA^{4-}$ ion of 0.20 M). If this solution is now made 0.10 M in H_2S and 0.10 M in H_3O^+, will PbS(s) precipitate?

49. Without performing detailed calculations, show why you would expect the concentrations of the various ammine–aqua complex ions to be negligible compared with that of $[Cu(NH_3)_4]^{2+}$ in a solution having a total Cu(II) concentration of 0.10 M and a total concentration of NH_3 of 1.0 M. Under what conditions would the concentrations of these ammine–aqua complex ions (such as $[Cu(H_2O)_3NH_3]^{2+}$) become more significant relative to the concentration of $[Cu(NH_3)_4]^{2+}$? Explain.

50. Verify the statement on page 1101 that neither Ca^{2+} nor Mg^{2+} found in natural waters is likely to precipitate from the water on the addition of other reagents if the ions are complexed with EDTA. Assume reasonable values for the total metal ion concentration and that of *free* EDTA, such as 0.10 M each.

51. Estimate the total $[Cl^-]$ required in a solution that is initially 0.10 M $CuSO_4$ to produce a visible yellow color.

$$\underset{\text{(blue)}}{[Cu(H_2O)_4]^{2+}} + 4\,Cl^- \rightleftharpoons \underset{\text{(yellow)}}{[CuCl_4]^{2-}} + 4\,H_2O$$

$$K_f = 4.2 \times 10^5$$

Assume that 99% conversion of $[Cu(H_2O)_4]^{2+}$ to $[CuCl_4]^{2-}$ is sufficient for this to happen, and ignore the presence of any mixed aqua–chloro complex ions.

52. Refer to the stability of $[Co(NH_3)_6]^{3+}(aq)$ on page 1098, and

(a) verify that E°_{cell} reaction (24.12) is +0.59 V.

(b) Calculate $[Co^{3+}]$ in a solution that has a total concentration of cobalt of 0.1 M and $[NH_3] = 0.1$ M.

(c) Show that for the value of $[Co^{3+}]$ calculated in part (b), reaction (24.12) will not occur. [*Hint:* Assume a low, but reasonable, concentration of Co^{2+} (say, 1×10^{-4} M) and a partial pressure of $O_2(g)$ of 0.2 atm.]

53. A Cu electrode is immersed in a solution that is 1.00 M NH_3 and 1.00 M in $[Cu(NH_3)_4]^{2+}$. If a standard hydrogen electrode is the cathode, E_{cell} is +0.08 V. What is the value obtained by this method for the formation constant, K_f, of $[Cu(NH_3)_4]^{2+}$?

54. The following concentration cell is constructed.

$$Ag|Ag^+(0.10\text{ M}[Ag(CN)_2]^-, 0.10\text{ M } CN^-)\,||Ag^+(0.10\text{ M})|Ag$$

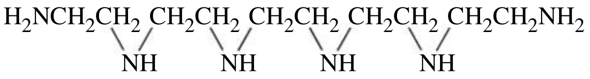
If K_f for $[Ag(CN)_2]^-$ is 5.6×10^{18}, what value would you expect for E_{cell}? [*Hint:* Recall that the anode is on the left.]

55. The compound $CoCl_2 \cdot 2\,H_2O \cdot 4\,NH_3$ may be one of the hydrate isomers $[CoCl(H_2O)(NH_3)_4]Cl \cdot H_2O$ or $[Co(H_2O)_2(NH_3)_4]Cl_2$. A 0.10 M aqueous solution of the compound is found to have a freezing point of −0.56 °C. Determine the correct formula of the compound. The freezing-point depression constant for water is 1.86 mol kg^{-1} °C, and for aqueous solutions, molarity and molality can be taken as approximately equal.

56. Explain why aqueous solutions of $[Sc(H_2O)_6]Cl_3$ and $[Zn(H_2O)_4]Cl_2$ are colorless, but an aqueous solution of $[Fe(H_2O)_6]Cl_3$ is not.

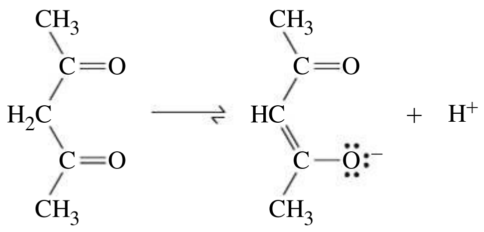
57. Provide a valence bond description of the bonding in the $Cr(NH_3)_6{}^{3+}$ ion. According to the valence bond description, how many unpaired electrons are there in the $Cr(NH_3)_6{}^{3+}$ complex? How does this prediction compare with that of crystal field theory?

58. The formation constants of the ions hexamminenickel(II), tris(ethylenediamine)nickel(II) and pentaethylenehexaminenickel(II) are $\beta_6 = 3.2 \times 10^8$, $\beta_3 = 1.6 \times 10^{18}$, and $\beta_1 = 2.0 \times 10^{19}$, respectively. Make reasonable assumptions concerning the enthalpy changes, and show that the formation constants illustrate the chelate effect. Pentaethylenehexamine (penten) is the hexadentate ligand shown below.



$$\mathrm{H_2NCH_2CH_2\underset{NH}{\diagdown\diagup}CH_2CH_2\underset{NH}{\diagdown\diagup}CH_2CH_2\underset{NH}{\diagdown\diagup}CH_2CH_2\underset{NH}{\diagdown\diagup}CH_2CH_2NH_2}$$

59. Acetyl acetone undergoes an isomerization to form a type of alcohol called an *enol.*



The enol, abbreviated acacH, can act as a bidentate ligand as the anion acac$^-$. Which of the following compounds are optically active: $Co(acac)_3$; *trans*-$[Co(acac)_2(H_2O)_2]Cl_2$; *cis*-$[Co(acac)_2(H_2O)_2]Cl_2$?

60. We have seen that complex formation can stabilize oxidation states. An important illustration of this fact is the oxidation of water in acidic solutions by $Co^{3+}(aq)$ but not by $[Co(en)_3]^{3+}$. Use the following data.

$$[Co(H_2O)_6]^{3+} + e^- \longrightarrow [Co(H_2O)_6]^{2+} \qquad E° = 1.82\ V$$

$$[Co(H_2O)_6]^{2+} + 3\ en \longrightarrow [Co(en)_3]^{2+} + 6\ H_2O(l) \qquad \log \beta_3 = 12.18$$

$$[Co(H_2O)_6]^{3+} + 3\ en \longrightarrow [Co(en)_3]^{3+} + 6\ H_2O(l) \qquad \log \beta_3 = 47.30$$

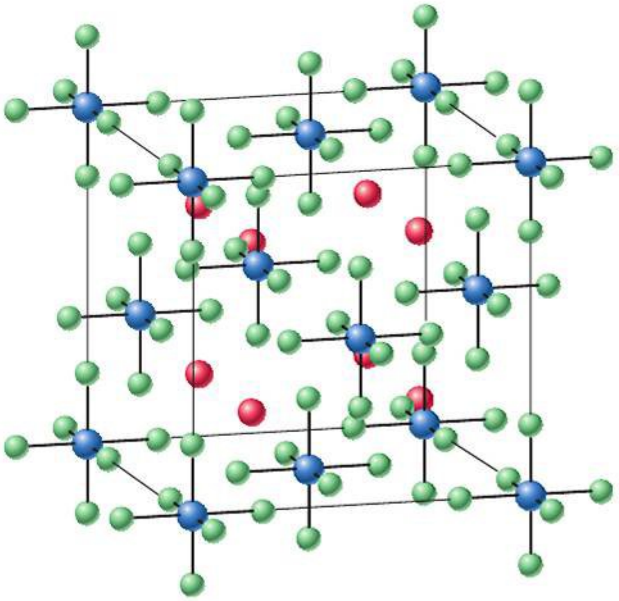
Calculate $E°$ for the reaction

$$[Co(en)_3]^{3+} + e^- \longrightarrow [Co(en)_3]^{2+}$$

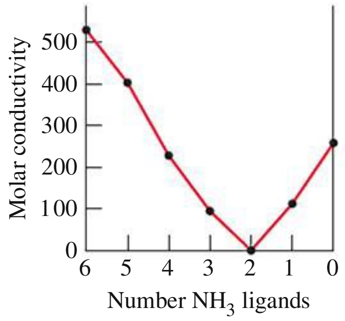
Show that $[Co(en)_3]^{3+}$ is stable in water but $Co^{3+}(aq)$ is not.

61. The amino acid glycine ($NH_2CH_2CO_2H$, denoted Hgly) binds as an anion and is a bidentate ligand. Draw and name all possible isomers of $[Co(gly)_3]$. How many isomers are possible for the compound $[Co(gly)_2Cl(NH_3)]$ [*Hint:* $NH_2CH_2CO_2{}^-$ is the glycinate anion.]

62. The structure of $K_2[PtCl_6]$ in the solid state is shown here. Identify the type of cubic unit cell, and describe the structure in terms of the holes occupied by the various ions.

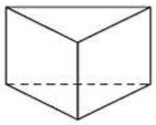


63. The graph below represents the molar conductivity of some Pt(IV) complexes. The ligands in these complexes are NH_3 molecules or Cl^- ions, the coordination number of Pt(IV) is 6, and the counter ions (for balancing charge) are K^+ or Cl^-. Write formulas for the coordination compounds corresponding to each point in the graph. (Molar conductivity is the electrical conductivity, under precisely defined conditions, of an aqueous solution containing one mole of a compound.)



Feature Problems

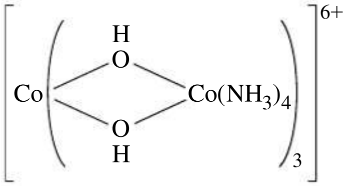
64. A structure that Werner examined as a possible alternative to the octahedron is the trigonal prism.



(a) Does this structure predict the correct number of isomers for the complex ion $[CoCl_2(NH_3)_4]^+$? If not, why not?

(b) Does this structure account for optical isomerism in $[Co(en)_3]^{3+}$? Explain.

65. Werner demonstrated that octahedral complexes can exhibit optical isomerism, and to Werner's satisfaction, this confirmed the octahedral arrangement of ligands. However, skeptics of his theory said that because the ligands contained carbon atoms, he could not rule out carbon as the source of the optical activity. Werner devised and prepared the following compound in which the OH^- groups act as bridging groups.



Werner resolved this compound into its optical isomers, confirming his theory and confounding his critics. What are the oxidation states of the Co ions? If the complex is low spin, what is the number of unpaired electrons in the molecule? Draw the structures of the two optical isomers.

66. The crystal field model discussed in the text describes how the degeneracy of the *d* orbitals is removed by an octahedral field of ligands. We have seen that the d_{xy}, d_{xz}, and d_{yz} orbitals are stabilized (lower energy) with respect to the average energy of the *d* orbitals and that the $d_{x^2-y^2}$ and d_{z^2} orbitals are destabilized. As described in Are You Wondering 24-3, the stabilization is $-0.4\ \Delta_o$ and destabilization is $0.6\ \Delta_o$. The crystal field stabilization energy (CFSE) can be defined as CFSE $= [(\text{number of electrons in the } d_{xy}, d_{xz}, \text{ and } d_{yz} \text{ orbitals}) \times (-0.4\ \Delta_o)] + [(\text{number of electrons in the } d_{x^2-y^2} \text{ and } d_{z^2} \text{ orbitals}) \times (0.6\ \Delta_o)]$. The following table contains the enthalpy of hydration for the reaction

$$M^{2+}(g) + 6\,H_2O(l) \longrightarrow [M(H_2O)_6]^{2+}(aq)$$

(a) Plot the hydration energies as a function of the atomic number of the metals shown.
(b) Assuming that all the hexaaqua complexes are high spin, which ions have zero CFSE?
(c) If lines are drawn between those ions with CFSE = 0, a line of negative slope is obtained. Can you explain this finding?

Dipositive Metal Ion	Hydration Energy, kJ mol^{-1}
Ca	−2468
Sc	−2673
Ti	−2750
V	−2814
Cr	−2799
Mn	−2743
Fe	−2843
Co	−2904
Ni	−2986
Cu	−2989
Zn	−2939

(d) The ions that do not have CFSE = 0 have heats of hydration that are more negative than the lines drawn in part (c). What is the explanation for this?
(e) Estimate the value of Δ_o for the Fe(II) ion in an octahedral field of water molecules.
(f) What wavelength of light would the $[Fe(H_2O)_6]^{2+}$ ion absorb?

Self-Assessment Exercises

67. In your own words, describe the following terms or symbols: **(a)** coordination number; **(b)** Δ_o; **(c)** ammine complex; **(d)** enantiomer.

68. Briefly describe each of the following ideas, phenomena, or methods: **(a)** spectrochemical series; **(b)** crystal field theory; **(c)** optical isomer; **(d)** structural isomerism.

69. Explain the important distinction between each of the following pairs: **(a)** coordination number and oxidation number; **(b)** monodentate and polydentate ligands; **(c)** *cis* and *trans* isomers; **(d)** dextrorotatory and levorotatory compounds; **(e)** low-spin and high-spin complexes.

70. The oxidation state of Ni in the complex ion $[Ni(CN)_4I]^{3-}$ is **(a)** −3; **(b)** −2; **(c)** 0; **(d)** +2; **(e)** +3.

71. The coordination number of Pt in the complex ion $[PtCl_2(en)_2]^{2+}$ is **(a)** 2; **(b)** 3; **(c)** 4; **(d)** 5; **(e)** 6.

72. Of the following complex ions, the one that exhibits isomerism is **(a)** $[Ag(NH_3)_2]^+$; **(b)** $[CoNO_2(NH_3)_5]^{2+}$; **(c)** $[Pt(en)(NH_3)_2]^{2+}$; **(d)** $[CoCl(NH_3)_5]^{2+}$; **(e)** $[PtCl_6]^{2-}$.

73. Of the following complex ions, the one that is optically active is **(a)** *cis*-$[CoCl_2(en)_2]^+$; **(b)** $[CoCl_2(NH_3)_4]^+$; **(c)** $[CoCl_4(NH_3)_2]^-$; **(d)** $[CuCl_4]^-$.

74. The number of unpaired electrons in the complex ion $[Cr(NH_3)_6]^{2+}$ is **(a)** 5; **(b)** 4; **(c)** 3; **(d)** 2; **(e)** 1.

75. Of the following, the one that is a Brønsted–Lowry acid is **(a)** $[Cu(NH_3)_4]^{2+}$; **(b)** $[FeCl_4]^-$; **(c)** $[Fe(H_2O)_6]^{3+}$; **(d)** $[Zn(OH)_4]^-$.

76. The most soluble of the following solids in $NH_3(aq)$ is **(a)** $Ca(OH)_2$; **(b)** $Cu(OH)_2$; **(c)** $BaSO_4$; **(d)** $MgCO_3$; **(e)** Fe_2O_3.

77. Name the following coordination compounds. Which one(s) exhibit(s) isomerism? Explain.
(a) $[CoBr(NH_3)_5]SO_4$
(b) $[Cr(NH_3)_6][Co(CN)_6]$
(c) $Na_3[Co(NO_2)_6]$
(d) $[Co(en)_3]Cl_3$

78. Write appropriate formulas for the following species.
(a) dicyanoargentate(I) ion
(b) triamminenitrito-*N*-platinum(II) ion
(c) aquachlorobis(ethylenediamine)cobalt(III) ion
(d) potassium hexacyanochromate(II)

79. Draw structures to represent these four complex ions: **(a)** $[PtCl_4]^{2-}$; **(b)** $[FeCl_4(en)]^-$; **(c)** *cis*-$[FeCl_2(ox)(en)]^-$; **(d)** *trans*-$[CrCl(OH)(NH_3)_4]^+$.

80. How many different structures are possible for each of the following complex ions?
(a) $[Co(H_2O)(NH_3)_5]^{3+}$
(b) $[Co(H_2O)_2(NH_3)_4]^{3+}$
(c) $[Co(H_2O)_3(NH_3)_3]^{3+}$
(d) $[Co(H_2O)_4(NH_3)_2]^{3+}$

81. Indicate what type of isomerism may be found in each of the following cases. If no isomerism is possible, so indicate.
(a) $[Zn(NH_3)_4][CuCl_4]$
(b) $[Fe(CN)_5SCN]^{4-}$
(c) $[NiCl(NH_3)_5]^+$
(d) $[PtBrCl_2(py)]^-$
(e) $[Cr(OH)_3(NH_3)_3]^-$

82. Indicate what type of isomerism may be found in each of the following cases. If no isomerism is possible, so indicate.
   - **(a)** $[\mathrm{Cr(en)_2Br_2}]^+$
   - **(b)** $[\mathrm{Co(ox)_2Br(SCN)}]^{3-}$
   - **(c)** $[\mathrm{NiCl_4(en)}]^{2-}$
   - **(d)** $[\mathrm{PtBrCl(ox)}]^-$
   - **(e)** $[\mathrm{Cr(Cl)_3(det)}]$, det is $\mathrm{H_2N(CH_2)_2NH(CH_2)_2NH_2}$

83. Of the complex ions $[\mathrm{Co(H_2O)_6}]^{3+}$ and $[\mathrm{Co(en)_3}]^{3+}$, one has a yellow color in aqueous solution; the other, blue. Match each ion with its expected color, and state your reason for doing so.

84. Using the method presented in Appendix E, construct a concept map depicting the essential ideas of crystal field theory, and how the theory explains the colors and magnetic properties of transition metal complexes.

25

Nuclear Chemistry

The thin strands of nebulosity are the remains of a star that ended its life in an enormous supernova explosion around 11,000 years ago. Near the center of this large shell of gas is a rapidly spinning neutron star believed to be the surviving core of the original star. Elementary particles, such as neutrons, and nuclear reactions, such as those occurring in stars, are discussed in this chapter.

25-7 Nuclear Stability
25-8 Nuclear Fission
25-9 Nuclear Fusion
25-10 Effect of Radiation on Matter
25-11 Applications of Radioisotopes

The origin of the elements is the stars, including our sun. Nuclear fusion in stars creates heavier elements from lighter ones. The heaviest elements, those with atomic numbers greater than 83, have unstable nuclei—that is, they are *radioactive.*

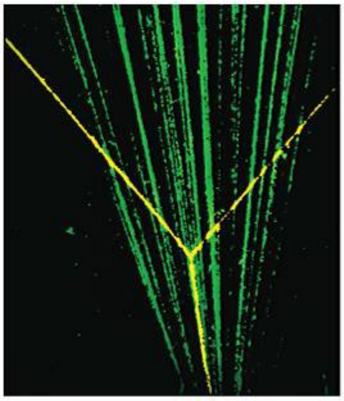
Certain isotopes of the lighter elements are also radioactive. The isotope carbon-14, for example, has chemical and physical properties that are essentially identical to those of the much more abundant isotopes carbon-12 and carbon-13. Carbon-14, however, is radioactive, and it is this property that is used in the technique known as radiocarbon dating.

In this chapter, we will consider a variety of phenomena that originate within the nuclei of atoms. Collectively, we refer to these phenomena as *nuclear chemistry*. Although stars are the natural source of all the elements, we will discuss how new heavy elements and radioactive isotopes of existing lighter elements can be made artificially. We will also discuss the effects of ionizing radiation on matter. These effects can have both positive and negative outcomes and are a subject of society's continuing nuclear debate.

◀ When radioactivity was first discovered, its dangers were not appreciated. The first workers in the area did not take the precautions that are routine today.

25-1 Radioactivity

The term *radioactivity* was proposed by Marie Curie to describe the emission of ionizing radiation by some of the heavier elements. Ionizing radiation, as the name implies, interacts with matter to produce ions. This means that the radiation is sufficiently energetic to break chemical bonds. Some ionizing radiation is particulate (consisting of particles), and some is nonparticulate. We introduced α, β, and γ radiation in Section 2-2. Let's describe them again in more detail, together with two other nuclear processes.



▲ Alpha particles leave a trail of liquid droplets, artificially colored green in this photograph, as they pass through a supersaturated vapor in a detector known as a cloud chamber. The chamber also contains He(g), and the trail of one α particle (yellow) is striking the nucleus of a He atom. Following the collision, the α particle and the He atom move apart along lines at about a 90° angle.

Alpha Particles

Alpha (α) particles are the nuclei of helium-4 atoms, $^{4}_{2}\text{He}^{2+}$, ejected spontaneously from the nuclei of certain radioactive atoms. We can think of α-particle emission as a process in which a bundle of two protons and two neutrons is emitted by a radioactive nucleus, resulting in a lighter nucleus. Alpha particles produce large numbers of ions via their collisions and near collisions with atoms as they travel through matter, but their penetrating power is low. (Generally, a few sheets of paper can stop them.) Because they have a positive charge, α particles are deflected by electric and magnetic fields (recall Figure 2-10).

We can represent the production of α particles by means of a nuclear equation. A **nuclear equation is** written to conform to two rules:

1. The sum of mass numbers must be the same on both sides.
2. The sum of atomic numbers must be the same on both sides.

In equation (25.1), the alpha particle is represented as $^{4}_{2}\text{He}$.

$$^{238}_{92}\text{U} \longrightarrow {}^{234}_{90}\text{Th} + {}^{4}_{2}\text{He} \tag{25.1}$$

Mass numbers total 238, and atomic numbers total 92. The loss of an α particle results in a *decrease* of 2 in the atomic number and 4 in the mass number of the nucleus.

KEEP IN MIND

that in a *nuclear* equation we represent only the nuclei of atoms, not the atoms as a whole. Although we do not keep track of electrons, electric charge is conserved by the requirement that the sums of the atomic numbers be the same on the two sides of the equation.

Beta Particles

Beta (β^-) particles are deflected by electric and magnetic fields in the *opposite* direction from α particles. They are less massive than α particles, so they are deflected more strongly than α particles (recall Figure 2-10). Also, they have a greater penetrating power through matter than do α particles (a book, rather than just a few sheets of paper, may be required to stop them). Beta $(-)$ particles are electrons, but they are electrons that originate from the nuclei of atoms in nuclear decay processes and are therefore extremely energetic. Electrons that surround the nucleus are given the familiar symbol, e^-.

The simplest decay process producing a β^- particle is the decay of a free neutron, which is unstable outside the nucleus of an atom.

$$^{1}_{0}\text{n} \longrightarrow {}^{1}_{1}\text{p} + {}^{0}_{-1}\beta + \nu \tag{25.2}$$

A β^- particle does not have an atomic number, but its 1− charge is equivalent to an atomic number of −1. In nuclear equations, the β^- particle is represented as $^{0}_{-1}\beta$. Also, a β^- particle is small enough, compared to protons and neutrons, that its mass can be ignored in most calculations. Equation (25.2) introduces the symbol ν to represent an entity called a *neutrino*. This particle was first postulated in the 1930s as necessary for the conservation of certain properties during the β^- decay process. Because they interact so weakly with matter, neutrinos were not detected until the 1950s. Even today, little is known of their properties, including their rest mass. (Rest mass is discussed on page 305).

▶ A neutrino has no charge and its detection was not easy. Theoretically, to balance nuclear equations, it was known that such a particle must exist. Many elementary particles have been found through experiments based on symmetry arguments.

For a typical β^- decay process, as represented by equation (25.3), we can think of a neutron *within* the nucleus of an atom spontaneously converting to a proton and an electron. This proton remains in the nucleus, whereas the electron is emitted as a β^- particle. Because of the extra proton, the atomic number *increases* by one unit, while the mass number is unchanged. The elusive neutrino is generally not included in the nuclear equation.

$$ {}^{234}_{90}\text{Th} \longrightarrow {}^{234}_{91}\text{Pa} + {}^{0}_{-1}\beta \tag{25.3} $$

In a similar manner, in some decay processes a *proton* within the nucleus is converted to a neutron, and a β^+ particle and a neutrino* are emitted.

$$ {}^{1}_{1}\text{p} \longrightarrow {}^{1}_{0}\text{n} + {}^{0}_{+1}\beta + \nu \tag{25.4} $$

The $\boldsymbol{\beta^+}$ particle, also called a **positron**, has properties similar to the β^- particle, except that it carries a *positive* charge. (See the photograph in the margin.) This particle is also known as a *positive electron* and is designated ${}^{0}_{+1}\beta$ in nuclear equations. Positron emission is commonly encountered with artificially produced radioactive nuclei of the lighter elements. For example,

$$ {}^{30}_{15}\text{P} \longrightarrow {}^{30}_{14}\text{Si} + {}^{0}_{+1}\beta \tag{25.5} $$

Electron Capture

Another process that achieves the same effect as positron emission is **electron capture (EC)**. In this case, an electron from an inner electron shell (usually the shell $n = 1$) is absorbed by the nucleus, where it converts a proton to a neutron. When an electron from a higher quantum level drops to the energy level vacated by the captured electron, X radiation is emitted. For example,

$$ {}^{202}_{81}\text{TI} + {}^{0}_{-1}\text{e} \longrightarrow {}^{202}_{80}\text{Hg (followed by X radiation)} \tag{25.6} $$

Gamma Rays

Some radioactive decay processes that yield α or β^- particles leave the nucleus in an excited state. The nucleus then loses energy in the form of electromagnetic radiation called gamma rays. **Gamma ($\boldsymbol{\gamma}$) rays** are a highly penetrating form of radiation that are *undeflected* by electric and magnetic fields (recall Figure 2-10). (Lead bricks more than several centimeters thick may be required to stop them.) In the radioactive decay of ${}^{234}_{92}\text{U}$, 77% of the nuclei emit α particles having an energy of 4.18 MeV. The remaining 23% of the ${}^{234}_{92}\text{U}$ nuclei produce α particles with energies of 4.13 MeV. In the latter case, the ${}^{230}_{90}\text{Th}$ nuclei are left with an excess energy of 0.05 MeV. This energy is released as γ rays. If the unstable excited Th nucleus is denoted as ${}^{230}_{90}\text{Th}^{\ddagger}$, we can write

$$ {}^{234}_{92}\text{U} \longrightarrow {}^{230}_{90}\text{Th}^{\ddagger} + {}^{4}_{2}\text{He} \tag{25.7} $$

$$ {}^{230}_{90}\text{Th}^{\ddagger} \longrightarrow {}^{230}_{90}\text{Th} + \gamma \tag{25.8} $$

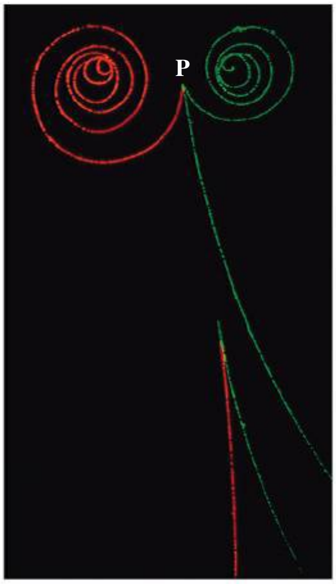
This γ-emission process is represented diagrammatically in Figure 25-1.

25-1 ARE YOU WONDERING...

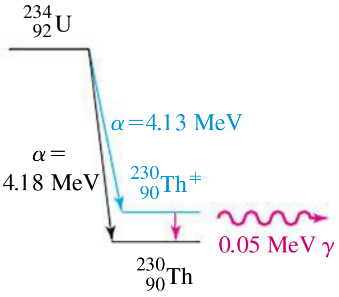
How an α particle gets out of a nucleus?

The answer has to do with quantum theory and the nature of the forces involved. Consider the potential energy diagram shown below. The blue line represents the potential energy, where we imagine an α particle as a separate particle within a nucleus such as ${}^{238}_{92}\text{U}$. Region A represents the potential energy of the α particle when it is held within the nucleus by the forces inside the uranium nucleus.

(continued)



▲ **A colorized cloud chamber photograph**
Point P marks an atomic nucleus that interacts with a γ-ray photon (not visible), producing a β^- particle and a positron (spiral green and red tracks, respectively). The photon also dislodges an orbital electron (vertical green track).



▲ FIGURE 25-1
Production of γ rays
The transition of a ${}^{230}_{90}\text{Th}$ nucleus between the two energy states shown results in the emission of 0.05 MeV of energy in the form of γ rays.

An electronvolt (eV) is the energy acquired by an electron when it falls through an electric potential difference of 1 volt:

$1 \text{ eV} = 1.6022 \times 10^{-19}$ J
$1 \text{ MeV} = 1 \times 10^{6}$ eV

---

*There appear to be two related entities: the neutrino and antineutrino. Neutrinos accompany positron emission and electron capture; antineutrinos are associated with β^- emission.

Region C represents the potential energy of the α particle when it is free of the nucleus. The potential energy along the downward curving portion of the blue line represents the Coulomb (electrostatic) repulsion between the positively charged α particle and the nucleus remaining after the α particle has escaped ($^{234}_{90}\text{Th}$).

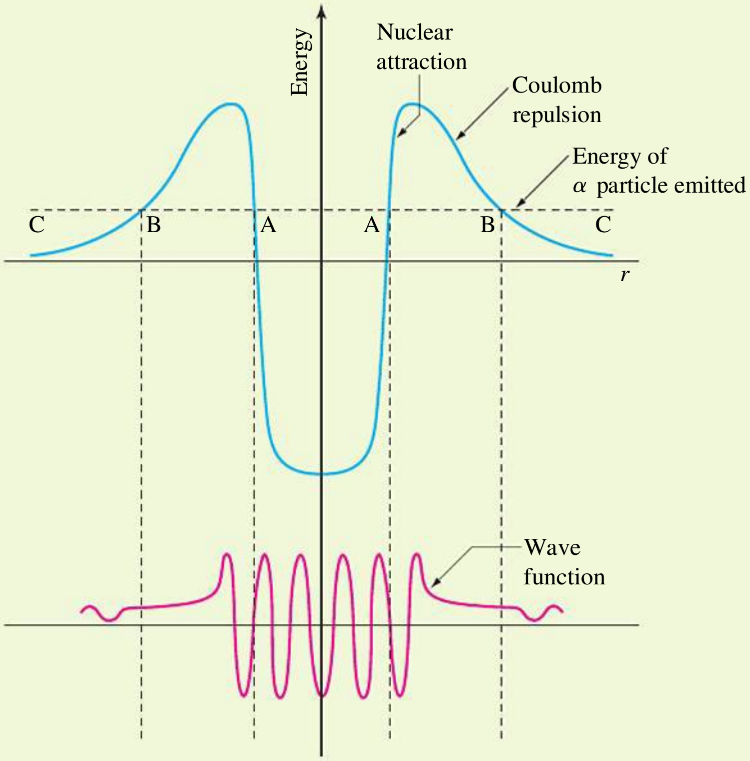
To get to region C, the α particle must get past the barrier in region B. The potential energy just beyond A, the radius of the nucleus, is greater than the energy of the α particle. (We know this from the measured energy of the α particle.) The α particle could not escape the nucleus if it were governed by classical physics because this would require an input of energy equal to the height of the barrier. Radioactive nuclei decay spontaneously, however, without an input of energy. How can the α particle get from region A to region C?

It passes through the barrier in a process known as *tunneling*. Classically, to go from A to C, the α particle would violate the principle of the conservation of energy. The α particle, however, possesses wave-like properties, as seen through the wave function at the bottom of the figure. Quantum mechanics predicts a finite probability of finding the α particle in a classically forbidden region. The wave function for the α particle trails off in the barrier region (B) and then reaches the outside, where it appears as a wave with much smaller amplitude. There is a finite probability (ψ^2) of finding the α particle outside the nucleus: The α particle has tunneled through the barrier.

Moreover, an alternative form of the uncertainty principle tells us that energy conservation can be violated by an amount ΔE for the length of time Δt given by

$$\Delta E \times \Delta t = \frac{h}{4\pi}$$

That is, the wave–particle duality of quantum theory allows the conservation of energy to be violated for brief periods—long enough for an α particle to tunnel through the barrier. ΔE corresponds to the energy difference between the barrier height and the α particle's energy, and Δt corresponds to the time required to pass through the barrier. The higher and wider the potential energy barrier, the less time the particle has to escape and the less likely it will do so. Thus, the height and width of the barrier control the rate of decay.



▲ Tunneling of an α particle out of the nucleus.

EXAMPLE 25-1 Writing Nuclear Equations for Radioactive Decay Processes

Write nuclear equations to represent **(a)** α-particle emission by ^{222}Rn and **(b)** radioactive decay of bismuth-215 to polonium-215.

Analyze

In part **(a)** we can identify two of the species involved in this process from the information given and we can write an incomplete equation. The unknown element in the incomplete equation is identified by determining the atomic number (Z) and mass number (A) that will balance the incomplete equation. Part **(b)** is done in a way very similar to that in part **(a)**.

Solve

(a) Since the $^{222}_{86}\text{Rn}$ nucleus ejects an α particle, $^{4}_{2}\text{He}$, as shown in the following incomplete nuclear equation.

$$^{222}_{86}\text{Rn} \longrightarrow ? + ^{4}_{2}\text{He}$$

Because the ejected α particle contains two protons, the unknown product must contain two fewer protons than $^{222}_{86}\text{Rn}$: $Z = 86 - 2 = 84$. This atomic number identifies the element as polonium, $_{84}\text{Po}$. The mass number (A) of the product can be obtained by subtracting the mass number of the α particle from that of the radon isotope: $A = 222 - 4 = 218$. The completed nuclear equation is

$$^{222}_{86}\text{Rn} \longrightarrow ^{218}_{84}\text{Po} + ^{4}_{2}\text{He}$$

(b) The atomic number of bismuth is 83 and that of polonium is 84. We can approach this problem as we did part **(a)**.

$$^{215}_{83}\text{Bi} \longrightarrow ^{215}_{84}\text{Po} + ?$$

There is no change in mass number, so the particle has a zero mass number. Its atomic number is $Z = 83 - 84 = -1$. Only a $^{0}_{-1}\beta$ particle fits these parameters: Beta $(-)$ decay is the only type of emission leading to an increase of one unit in atomic number without a change in the mass number.

$$^{215}_{83}\text{Bi} \longrightarrow ^{215}_{84}\text{Po} + ^{0}_{-1}\beta$$

Assess

It is interesting that when starting from different elements, we can arrive at the same element through different types of particle emission. Note that even though we came to the same decayed element, we ended with different isotopes of that element.

PRACTICE EXAMPLE A: Write a nuclear equation to represent β^--particle emission by $^{241}_{94}\text{Pu}$.

PRACTICE EXAMPLE B: Write a nuclear equation to represent the decay of a radioactive nucleus to produce ^{58}Ni and a positron.

25-1 CONCEPT ASSESSMENT

Which type(s) of radioactive decay transform(s) the nucleus of an atom to that of a different element, and which type(s) do not?

25-2 Naturally Occurring Radioactive Isotopes

Of the stable nuclides, $^{209}_{83}\text{Bi}$ has the highest atomic number and mass number. All known nuclides beyond it in atomic and mass numbers are radioactive. Naturally occurring $^{238}_{92}\text{U}$ is radioactive and disintegrates by the loss of α particles.

$$^{238}_{92}\text{U} \longrightarrow ^{234}_{90}\text{Th} + ^{4}_{2}\text{He}$$

KEEP IN MIND

that *nuclide* is the general term for an atom with a particular atomic number and mass number. Different nuclides of an element are referred to as *isotopes*.

$^{234}_{90}$Th is also radioactive; it decays by β^- emission.

$$^{234}_{90}\text{Th} \longrightarrow {}^{234}_{91}\text{Pa} + {}^{0}_{-1}\beta$$

$^{234}_{91}$Pa also decays by β^- emission to produce $^{234}_{92}$U, which is also radioactive.

$$^{234}_{91}\text{Pa} \longrightarrow {}^{234}_{92}\text{U} + {}^{0}_{-1}\beta$$

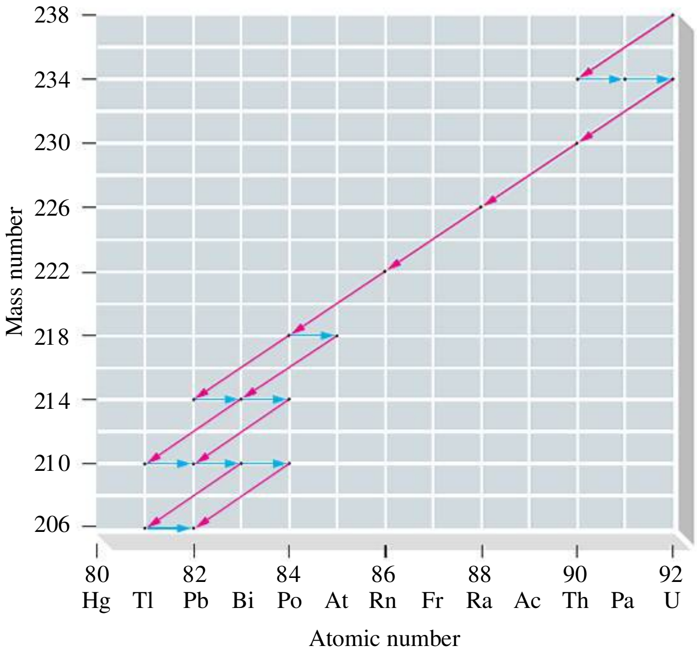
The term *daughter* is commonly used to describe the new nuclide produced in a radioactive decay. Thus, ^{234}Th is the daughter of ^{238}U, ^{234}Pa is the daughter of ^{234}Th, and so on.

The chain of radioactive decay that begins with $^{238}_{92}$U continues through a number of steps of α and β^- emission until it eventually terminates with a stable isotope of lead—$^{206}_{82}$Pb. The entire scheme is outlined in Figure 25-2. All naturally occurring radioactive nuclides of high atomic number belong to one of three **radioactive decay series**: the *uranium* series just described, the *thorium* series, or the *actinium* series. (The actinium series actually begins with uranium-235, which was once called actino-uranium.)

Even though some of the daughters in natural radioactive decay schemes have very short half-lives, all are present because they are constantly forming as well as decaying. It is likely that only about one gram of radium-226 was present in several tons of uranium ore processed by Marie Curie in her discovery of radium in 1898. Nevertheless, she was successful in isolating it. The ore also contained only a fraction of a milligram of polonium, which she was able to detect but not isolate.

Radioactive decay schemes can be used to determine the ages of rocks and thereby the age of Earth (see Section 25-5). The appearance of certain radioactive substances in the environment can also be explained through radioactive decay series. The nuclides ^{210}Po and ^{210}Pb have been detected in cigarette smoke. These radioactive isotopes are derived from ^{238}U, found in trace amounts in the phosphate fertilizers used in tobacco fields. These α-emitting isotopes have been implicated in the link between cigarette smoking and cancer and heart disease.

▲ **Marie Sklodowska Curie (1867–1934)**
Marie Curie shared the 1903 Nobel Prize in physics for studies on radiation phenomena. In 1911, she won the Nobel Prize in chemistry for her discovery of polonium and radium.



▲ FIGURE 25-2
The natural radioactive decay series for $^{238}_{92}$U (uranium series)
The long arrows pointing down and to the left correspond to α-particle emissions. The short horizontal arrows represent β^- emissions. Other natural decay series originate with $^{232}_{90}$Th (thorium series) and $^{235}_{92}$U (actinium series).

Radioactivity, which is so common among isotopes of high atomic number, is a relatively rare phenomenon among the naturally occurring lighter isotopes. Even so, ^{40}K is a radioactive isotope, as are ^{50}V and ^{138}La. ^{40}K decays by β^- emission and by electron capture.

$$^{40}_{19}\mathrm{K} \longrightarrow {}^{40}_{20}\mathrm{Ca} + {}^{0}_{-1}\beta \qquad \text{and} \qquad {}^{40}_{19}\mathrm{K} + {}^{0}_{-1}\mathrm{e} \longrightarrow {}^{40}_{18}\mathrm{Ar}$$

At the time Earth was formed ^{40}K was much more abundant than it is now. It is believed that the high argon content of the atmosphere (0.934% by volume and almost all of it as ^{40}Ar) is derived from the radioactive decay of ^{40}K. Aside from ^{40}K and ^{14}C (produced by cosmic radiation), the most important radioactive isotopes of the lighter elements are produced *artificially*.

25-2 CONCEPT ASSESSMENT

Explain why francium, the heaviest of the alkali metals (group 1), is not found in minerals containing the other alkali metals and is also one of the rarest elements.

25-3 Nuclear Reactions and Artificially Induced Radioactivity

Ernest Rutherford discovered that atoms of one element can be transformed into atoms of another element. He did this in 1919 by bombarding $^{14}_{7}N$ nuclei with α particles, producing $^{17}_{8}O$ and protons. In this way, he was able to obtain protons outside atomic nuclei. The process can be represented as

$$^{14}_{7}\mathrm{N} + {}^{4}_{2}\mathrm{He} \longrightarrow {}^{17}_{8}\mathrm{O} + {}^{1}_{1}\mathrm{H} \qquad \textbf{(25.9)}$$

In reaction (25.9), instead of a nucleus disintegrating spontaneously, it must be struck by another small particle to induce a nuclear reaction. $^{17}_{8}O$ is a naturally occurring *nonradioactive* isotope of oxygen (0.037% natural abundance). The situation with $^{30}_{15}P$, which can also be produced by a nuclear reaction, is somewhat different.

In 1934, when bombarding aluminum with α particles, Iréne Joliot-Curie (daughter of Marie and Pierre Curie) and her husband, Frédéric Joliot, observed the emission of two types of particles: neutrons and positrons. The Joliots observed that when bombardment by α particles was stopped, the emission of neutrons also stopped; the emission of positrons continued, however. Their conclusion was that the nuclear bombardment produces $^{30}_{15}P$, which undergoes radioactive decay by the emission of positrons.

$$^{27}_{13}\mathrm{Al} + {}^{4}_{2}\mathrm{He} \longrightarrow {}^{30}_{15}\mathrm{P} + {}^{1}_{0}\mathrm{n}$$

$$^{30}_{15}\mathrm{P} \longrightarrow {}^{30}_{14}\mathrm{Si} + {}^{0}_{+1}\beta$$

The first radioactive nuclide obtained by artificial means was $^{30}_{15}P$. Now, over 1000 artificially radioactive nuclides have been produced, and their number considerably exceeds the number of nonradioactive ones (about 280).

▲ **Iréne Joliot-Curie (1897–1956)**
Iréne Joliot-Curie and her husband, Frédéric Joliot, shared the 1935 Nobel Prize in chemistry for the artificial production of radioactive nuclides.

EXAMPLE 25-2 Writing Equations for Nuclear Bombardment Reactions

Write a nuclear equation for the production of ^{56}Mn by bombardment of ^{59}Co with neutrons.

Analyze

In this example we proceed in a manner similar to that in Example 25-1: We first write an incomplete nuclear equation from the given information. We must also realize that a particle is produced along with ^{56}Mn. To find the mass number (A) of the unknown particle, we must subtract the mass number of the Mn atom from that of

(continued)

the Co atom plus the neutron that initiates the reaction. Thus, for the unknown particle, $A = 59 + 1 - 56 = 4$. Subtracting the atomic number of Mn from that of Co provides the atomic number of the unknown particle: $Z = 27 - 25 = 2$.

Solve

The unknown particle must have $A = 4$ and $Z = 2$; it is an α particle.

$$^{59}_{27}\text{Co} + ^{1}_{0}\text{n} \longrightarrow ^{56}_{25}\text{Mn} + ^{4}_{2}\text{He}$$

Assess

By using the concept that a balanced nuclear equation has the same overall atomic number and mass number on both sides of the equation, we can identify the unknown particle that has been ejected during bombardment.

PRACTICE EXAMPLE A: Write a nuclear equation for the production of ^{147}Eu by bombardment of ^{139}La with ^{12}C.

PRACTICE EXAMPLE B: Write a nuclear equation for the production of ^{124}I by bombardment of ^{121}Sb with α particles. Also, write an equation for the subsequent decay of ^{124}I by positron emission.

25-4 Transuranium Elements

Until 1940, the only known elements were those that occur naturally. In 1940, bombardment of $^{238}_{92}$U atoms with neutrons produced the first synthetic element. First, the unstable nucleus $^{239}_{92}$U forms. This nucleus then undergoes β^- decay, yielding the element neptunium, with $Z = 93$.

$$^{238}_{92}\text{U} + ^{1}_{0}\text{n} \longrightarrow ^{239}_{92}\text{U} + \gamma$$

$$^{239}_{92}\text{U} \longrightarrow ^{239}_{93}\text{Np} + ^{0}_{-1}\beta$$

Bombardment by neutrons is an effective way to produce nuclear reactions because these heavy uncharged particles are not repelled as they approach a nucleus.

Since 1940, all the elements from $Z = 93$ to 112, as well as elements 114 and 116, have been synthesized. Many of the new elements of high atomic number have been formed by bombarding transuranium atoms with the nuclei of lighter elements. For example, an isotope of the element $Z = 105$ can be produced by bombarding atoms of $^{249}_{98}$Cf with $^{15}_{7}$N nuclei.

$$^{249}_{98}\text{Cf} + ^{15}_{7}\text{N} \longrightarrow ^{260}_{105}\text{Db} + 4\,^{1}_{0}\text{n} \qquad \textbf{(25.10)}$$

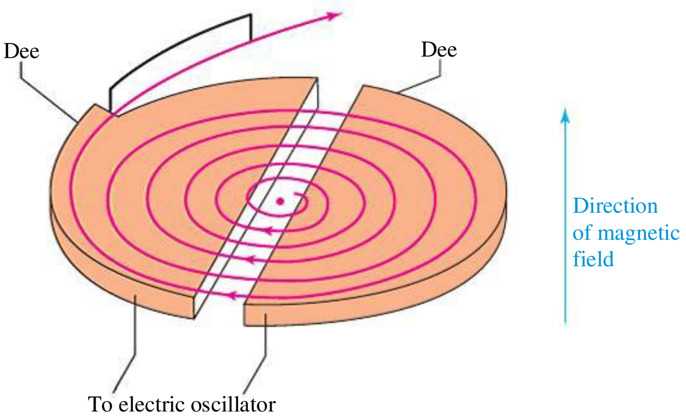
▲ Stanford Linear Accelerator Center (SLAC0 PEP-II collider). Electrons (blue) and positrons (pink) circulate in opposite directions along the two rings before being forced to collide. These collisions produce large quantities of subatomic particles (e.g., "B mesons and anti-B mesons").

To bring about nuclear reactions such as (25.10) requires bombarding atomic nuclei with energetic particles. Such energetic particles can be obtained in an accelerator. A type of accelerator known as a cyclotron is illustrated in Figure 25-3.

A *charged-particle accelerator*, as the name implies, can produce only beams of charged particles (such as $^{1}_{1}\text{H}^{+}$) as projectiles. In many cases, neutrons are most effective as projectiles for nuclear bombardment. The neutrons required can be generated through a nuclear reaction produced by a charged-particle beam. In the following reaction, $^{2}_{1}$H represents a beam of deuterons (actually, $^{2}_{1}\text{H}^{+}$) from an accelerator.

$$^{9}_{4}\text{Be} + ^{2}_{1}\text{H} \longrightarrow ^{10}_{5}\text{B} + ^{1}_{0}\text{n}$$

Another important source of neutrons for nuclear reactions is a nuclear reactor (as we will see in Section 25-8).



▲ FIGURE 25-3
The cyclotron
This type of accelerator consists of two hollow, flat, semicircular boxes, called *dees*, that are kept electrically charged. The entire assembly is maintained within a magnetic field. The particles to be accelerated, in the form of positive ions, are produced at the center of the opening between the dees. They are then attracted into the negatively charged dee and forced into a circular path by the magnetic field. When the particles leave the dee and enter the gap, the electric charges on the dees are reversed, so that the particles are attracted into the opposite dee. The particles are accelerated as they pass the gap and travel a wider circular path in the new dee. This process is repeated many times until the particles are brought to the required energy.

25-5 Rate of Radioactive Decay

In time, we can expect every atomic nucleus of a radioactive nuclide to disintegrate, but it is impossible to predict when any one nucleus will do so. Although we cannot make predictions for a particular atom, we can use statistical methods to make predictions for a collection of atoms. Based on experimental observations, a **radioactive decay law** has been established.

The rate of disintegration of a radioactive material—called the activity, A, *or the* decay rate*—is directly proportional to the number of atoms present.*

In mathematical terms,

$$\text{rate of decay} \propto N \quad \text{and} \quad \text{rate of decay} = A = \lambda N \qquad \textbf{(25.11)}$$

The activity is expressed in atoms per unit time, such as atoms per second. N is the number of atoms in the sample being observed; $\boldsymbol{\lambda}$ is the **decay constant**, which has units of time^{-1}. Consider the case of a 1,000,000-atom sample disintegrating at the rate of 100 atoms per second. In such a case, $N = 1.0 \times 10^6$ and

$$\lambda = A/N = 100 \text{ atom s}^{-1}/1.0 \times 10^6 \text{ atom} = 1.0 \times 10^{-4}\ \text{s}^{-1}$$

Radioactive decay is a *first-order* process. To relate it to the first-order kinetics that we studied in Chapter 14, think of the activity as corresponding to a rate of reaction; the number of atoms as corresponding to the concentration of a reactant; and the decay constant, λ, as corresponding to a rate constant, k. This correspondence can be carried further by writing an integrated radioactive decay law and a relationship between the decay constant and the **half-life** of the process—the length of time required for half of a radioactive sample to disintegrate.

$$\ln\left(\frac{N_t}{N_0}\right) = -\lambda t \tag{25.12}$$

$$t_{1/2} = \frac{0.693}{\lambda} \tag{25.13}$$

In these equations, N_0 represents the number of atoms at some initial time $(t = 0)$; N_t is the number of atoms at some later time, t; λ is the decay constant; and $t_{1/2}$ is the half-life.

Recall from Chapter 14 (page 615) that the half-life of a first-order process is a *constant*. Thus, if half the atoms of a radioactive sample disintegrate in 2.5 min, the number of atoms remaining will be reduced to one-fourth the original number in 5.0 min, one-eighth in 7.5 min, and so on. The shorter the half-life, the larger the value of λ and the faster the decay process. Half-lives of radioactive nuclides range from extremely short to very long, as suggested by the representative data in Table 25.1.

You may be wondering whether, like first-order chemical reactions, radioactive decay is temperature dependent. We learned in Chapter 14 that an important determinant of the rate of a chemical reaction is the height of the energy barrier between the reactants and products (the activation energy). The higher the temperature, the greater the number of molecules that can surmount the barrier as a result of collisions and the faster the reaction proceeds. Although there is also an energy barrier that confines nuclear particles to the nucleus, molecular collisions do not invest any energy in nuclear particles. Moreover, in radioactive decay, nuclear particles do not escape the nucleus by surmounting an energy barrier—they tunnel through it. Thus, the rates of radioactive decay processes are independent of temperature.

TABLE 25.1 Some Representative Half-Lives

Nuclide	Half-Life[a]	Nuclide	Half-Life[a]	Nuclide	Half-Life[a]
${}^{3}_{1}\text{H}$	12.26 y	${}^{40}_{19}\text{K}$	1.25×10^{9} y	${}^{214}_{84}\text{Po}$	1.64×10^{-4} s
${}^{14}_{6}\text{C}$	5730 y	${}^{80}_{35}\text{Br}$	17.6 min	${}^{222}_{86}\text{Rn}$	3.823 d
${}^{13}_{8}\text{O}$	8.7×10^{-3} s	${}^{90}_{38}\text{Sr}$	27.7 y	${}^{226}_{88}\text{Ra}$	1.60×10^{3} y
${}^{28}_{12}\text{Mg}$	21 h	${}^{131}_{53}\text{I}$	8.040 d	${}^{234}_{90}\text{Th}$	24.1 d
${}^{32}_{15}\text{P}$	14.3 d	${}^{137}_{55}\text{Cs}$	30.23 y	${}^{238}_{92}\text{U}$	4.51×10^{9} y
${}^{35}_{16}\text{S}$	88 d				

[a] s, second; min, minute; h, hour; d, day; y, year.

EXAMPLE 25-3 Using the Half-Life Concept and the Radioactive Decay Law to Describe the Rate of Radioactive Decay

The phosphorus isotope ${}^{32}\text{P}$ is used in biochemical studies to determine the pathways of phosphorus atoms in living organisms. Its presence is detected through its emission of β^- particles. **(a)** What is the decay constant for ${}^{32}\text{P}$, expressed in the unit s^{-1}? **(b)** What is the activity of a 1.00 mg sample of ${}^{32}\text{P}$ (that is, how many atoms disintegrate per second)? **(c)** Approximately what mass of ${}^{32}\text{P}$ will remain in the original 1.00 mg sample after 57 days? (See Table 25.1.) **(d)** What will be the rate of radioactive decay after 57 days?

Analyze

To solve these types of problems, we need to determine the decay constant, λ, of the radioactive species, which is related to the concept of half-life through equation (25.13). After determining the decay constant from the half-life of the sample, we can then use it to determine the activity for part **(b)**.

Solve

(a) We can determine λ from $t_{1/2}$ with equation (25.13). The first result we get has the unit d^{-1}. We must convert this unit to h^{-1}, min^{-1}, and s^{-1}.

$$\lambda = \frac{0.693}{14.3\text{ d}} \times \frac{1\text{ d}}{24\text{ h}} \times \frac{1\text{ h}}{60\text{ min}} \times \frac{1\text{ min}}{60\text{ s}} = 5.61 \times 10^{-7}\text{ s}^{-1}$$

(b) First, let us find the number of atoms, N, in 1.00 mg of ^{32}P.

$$\begin{aligned} N(^{32}\text{P atoms}) &= 0.00100\text{ g} \times \frac{1\text{ mol }^{32}\text{P}}{32.0\text{ g}} \times \frac{6.022 \times 10^{23}\ ^{32}\text{P atoms}}{1\text{ mol }^{32}\text{P}} \\ &= 1.88 \times 10^{19}\ ^{32}\text{P atoms} \end{aligned}$$

Then, we can multiply this number by the decay constant to get the activity or decay rate.

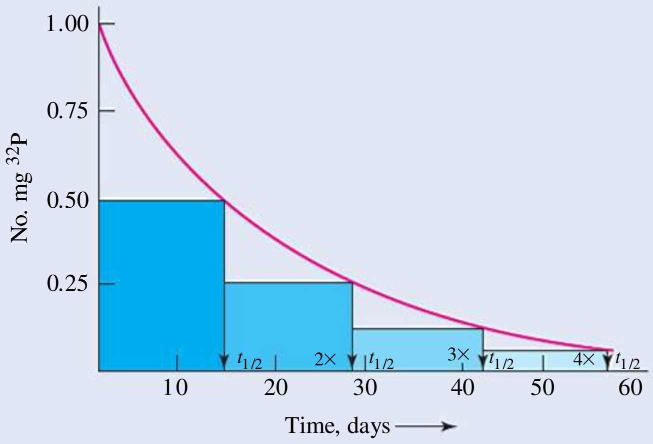
$$\begin{aligned} \text{activity} &= \lambda N = 5.61 \times 10^{-7}\text{ s}^{-1} \times 1.88 \times 10^{19}\text{ atoms} \\ &= 1.05 \times 10^{13}\text{ atoms/s} \end{aligned}$$

(c) A period of 57 days is $57/14.3 = 4.0$ half-lives. As shown in Figure 25-4, the quantity of radioactive material decreases by one-half for every half-life. The quantity remaining is $\left(\frac{1}{2}\right)^4$ of the original quantity.

$$?\text{ mg }^{32}\text{P} = 1.00\text{ mg} \times \left(\frac{1}{2}\right)^4 = 1.00\text{ mg} \times \frac{1}{16} = 0.063\text{ mg }^{32}\text{P}$$

(d) The activity is directly proportional to the number of radioactive atoms remaining (activity $= \lambda N$), and the number of atoms is directly proportional to the mass of ^{32}P. When the mass of ^{32}P has dropped to one-sixteenth its original mass, the number of ^{32}P atoms also falls to one-sixteenth the original number, and the rate of decay is one-sixteenth the original activity.

$$\text{rate of decay} = \frac{1}{16} \times 1.05 \times 10^{13}\text{ atoms/s} = 6.56 \times 10^{11}\text{ atoms/s}$$



▲ FIGURE 25-4
Radioactive decay of a hypothetical ^{32}P sample—Example 25-3 illustrated

Assess

Phosphorus-32 isotope is an ideal radionuclide to use because of its short half-life. This time is long enough to carry out experiments, yet short enough that disposal is not a major problem. We see in this example that after 57 days, approximately 6% of the original mass of phosphorus remains.

PRACTICE EXAMPLE A: ^{131}I is a β^- emitter used as a tracer for radioimmunoassays in biological systems. Use information in Table 25.1 to determine **(a)** the decay constant in s^{-1}; **(b)** the activity of a 2.05 mg sample of ^{131}I; **(c)** the percentage of ^{131}I remaining after 16 days; and **(d)** the rate of β^- emission after 16 days.

PRACTICE EXAMPLE B: ^{223}Ra has a half-life of 11.4 days. How long would it take for the activity associated with a sample of ^{223}Ra to decrease to 1.0% of its current value?

25-3 CONCEPT ASSESSMENT

Why are radioactive nuclides with intermediate half-lives generally more hazardous than those with either extremely short or extremely long half-lives?

Radiocarbon Dating

In the upper atmosphere, ${}^{14}_{6}C$ is formed at a constant rate by the bombardment of ${}^{14}_{7}N$ with neutrons.

$$ {}^{14}_{7}N + {}^{1}_{0}n \longrightarrow {}^{14}_{6}C + {}^{1}_{1}H $$

The neutrons are produced by cosmic rays. ${}^{14}_{6}C$ disintegrates by β^- emission.

Carbon-containing compounds in living organisms are in equilibrium with ${}^{14}C$ in the atmosphere—that is, these organisms replace ${}^{14}C$ atoms that have undergone radioactive decay with "fresh" ${}^{14}C$ atoms through interactions with their environment. The ${}^{14}C$ isotope is radioactive and has a half-life of 5730 years. The activity associated with ${}^{14}C$ that is in equilibrium with its

EXAMPLE 25-4 Applying the Integrated Rate Law for Radioactive Decay: Radiocarbon Dating

A wooden object found in an Indian burial mound is subjected to radiocarbon dating. The activity associated with its ${}^{14}C$ content is 10 dis min^{-1} g^{-1}. What is the age of the object? In other words, how much time has elapsed since the tree from which the wood came was cut down?

Analyze

The solution requires three equations: (25.11), (25.12), and (25.13).

Solve

Equation (25.13) is used to determine the decay constant.

$$ \lambda = \frac{0.693}{5730\ \text{y}} = 1.21 \times 10^{-4}\ \text{y}^{-1} $$

Next, equation (25.11) relates to the actual number of atoms: N at $t = 0$ (the time when the ${}^{14}C$ equilibrium was destroyed) and N_t at time t (the present time). As discussed on page 1123, the activity just before the ${}^{14}C$ equilibrium was destroyed was 15 dis min^{-1} g^{-1}; at the time of the measurement, it is 10 dis min^{-1} g^{-1}. The corresponding numbers of atoms are equal to these activities divided by λ.

$$ N_0 = A_0/\lambda = 15/\lambda \quad \text{and} \quad N_t = A_t/\lambda = 10/\lambda $$

Finally, we substitute into equation (25.12).

$$ \ln\frac{N_t}{N_0} = \ln\frac{10/\lambda}{15/\lambda} = \ln\frac{10}{15} = -(1.21 \times 10^{-4}\ \text{y}^{-1})t $$

$$ -0.41 = -(1.21 \times 10^{-4}\ \text{y}^{-1})t $$

$$ t = \frac{0.41}{1.21 \times 10^{-4}\ \text{y}^{-1}} = 3.4 \times 10^{3}\ \text{y} $$

Assess

In the previous example, we observed that the activity depends on the amount of material. Therefore, the results of radiocarbon dating depend on knowing the activity at the time the equilibrium between ${}^{14}C$ and the other nonradioactive carbon isotopes ceases. If at the time equilibrium was destroyed the activity was 14 dis min^{-1} g^{-1}, we would have determined the object to be 2.8×10^3 years old, which is approximately a 17% error.

PRACTICE EXAMPLE A: What is the age of a mummy, given a ${}^{14}C$ activity of 8.5 dis min^{-1} g^{-1}?

PRACTICE EXAMPLE B: What should be the current activity, in dis min^{-1} g^{-1}, of a wooden object believed to be 1100 years old?

◀ The remains of a man frozen in a glacier in the Austrian Alps have been dated by the radiocarbon method as 5300 years old.

environment is about 15 disintegrations per minute (dis min^{-1}) per gram of carbon. When an organism dies (for instance, when a tree is cut down), this equilibrium is destroyed and the disintegration rate falls off because the dead organism no longer absorbs new ^{14}C. From the measured disintegration rate at some later time, the age can be estimated (that is, the elapsed time since the ^{14}C equilibrium was disrupted).

The Age of Earth

The natural radioactive decay scheme of Figure 25-2 suggests the eventual fate of all $^{238}_{92}\text{U}$ in nature—conversion to lead. Naturally occurring uranium minerals always have associated with them some nonradioactive lead formed by radioactive decay. From the mass ratio of $^{206}_{82}\text{Pb}$ to $^{238}_{92}\text{U}$ in such a mineral, it is possible to estimate the age of the igneous rock containing the mineral. The age of the rock refers to the time elapsed since molten magma solidified to form the rock. One assumption of this method is that the initial radioactive nuclide, the final stable nuclides, and all the products of a decay series remain in the rock. Another assumption is that any lead present in the rock initially consisted of the several isotopes of lead in their present, naturally occurring abundances.

▲ A lunar rock that has been radiometrically dated to be about 4.6 billion years old.

The half-life of $^{238}_{92}\text{U}$ is 4.5×10^9 years. According to the natural decay scheme of Figure 25-2, the basic change that occurs as atoms of $^{238}_{92}\text{U}$ and its daughters pass through the entire sequence of steps is

$$^{238}_{92}\text{U} \longrightarrow {}^{206}_{82}\text{Pb} + 8\,{}^{4}_{2}\text{He} + 6\,{}^{0}_{-1}\beta$$

The decay sequence for $^{238}\text{U} \longrightarrow {}^{206}\text{Pb}$ has 14 steps. The first step, however, has a much longer half-life than any of the other steps in the series and can thus be thought of as the rate-determining step, with the subsequent steps being "fast." As discussed in Chapter 14, we can ignore the effect on the overall rate of fast steps that occur after the slow, rate-determining step. Thus, the half-life for ^{238}U is essentially equal to the time it takes to convert half the initial ^{238}U to the ^{206}Pb isotope. Discounting the mass associated with the β^- particles, for every 238 g of uranium that undergoes complete decay, 206 g of lead and 32 g of helium are produced.

Suppose that in a hypothetical rock containing no lead initially, 1.000 g of $^{238}_{92}\text{U}$ had disintegrated through one half-life, 4.51×10^9 years. At the end of that time, 0.500 g $^{238}_{92}\text{U}$ would have disintegrated and another 0.500 g would remain. The quantity of $^{206}_{82}\text{Pb}$ now present in the rock would be

$$0.500\text{ g }{}^{238}_{92}\text{U} \times \frac{206\text{ g }{}^{206}_{82}\text{Pb}}{238\text{ g }{}^{238}_{92}\text{U}} = 0.433\text{ g }{}^{206}_{82}\text{Pb}$$

The ratio of lead-206 to uranium-238 in the rock would be

$$^{206}_{82}\text{Pb}/{}^{238}_{92}\text{U} = 0.433/0.500 = 0.866$$

If the $^{206}_{82}\text{Pb}/{}^{238}_{92}\text{U}$ mass ratio is less than 0.866, the age of the rock is less than one half-life of $^{238}_{92}\text{U}$. A higher ratio indicates a greater age for the rock. The best estimates of the age of the oldest rocks, and presumably of Earth itself, are about 4.5 × 10^9 years. These estimates are based on the $^{206}_{82}\mathrm{Pb}/^{238}_{92}\mathrm{U}$ ratio and on ratios for other pairs of isotopes from natural radioactive decay series.

Modern Radioactive Dating (Geochronology)

Modern radioactive dating techniques use mass spectrometry to analyze parent or daughter nuclides, or both. A mass spectrometer (described in Chapter 2) can be used to determine the amount of the various isotopes found in geological material (e.g., rocks), and that data can be used to calculate the age of the material. One particular pair of isotopes currently used in dating geological material is potassium-40 and argon-40. Potassium-40 is radioactive and mainly undergoes β-decay to calcium-40; however, some potassium-40 undergoes electron capture and decays to argon-40. Attempts have been made to perform radiodating for the potassium-40–calcium-40 pair, but this is not currently possible because of the large natural abundance of calcium.

Let us look at how isotope pairs can be used to determine the age of geological material. We begin by rewriting equation (25.12) as

$$N = N_0 \mathrm{e}{-}\lambda t \tag{25.14}$$

where N is the number of atoms currently present, N_0 is the initial number of atoms at $t = 0$, and λ is the decay constant for $^{40}\mathrm{K}$. Since we don't know how many atoms were present at $t = 0$, we can determine that by recognizing that

$$N_0 = N + D \tag{25.15}$$

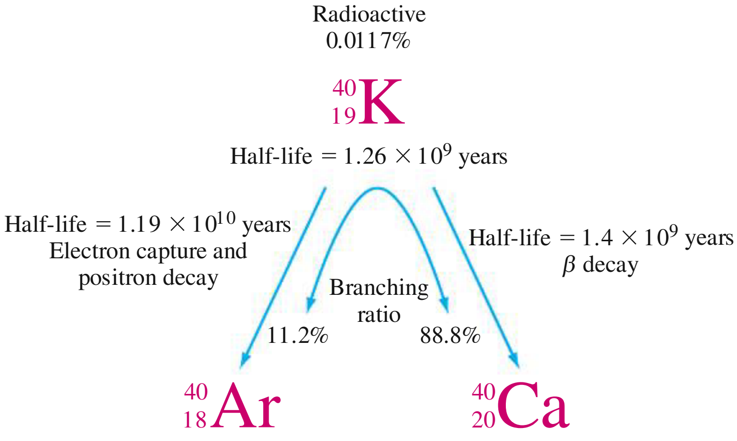
where D is the number of daughter atoms, that is, the atoms resulting from the decay of an isotope. An example of a daughter atom is $^{40}\mathrm{Ar}$, which is a daughter atom of $^{40}\mathrm{K}$. Combining equations (25.14) and (25.15) and solving for t we have

$$t = \frac{1}{\lambda}\ln\left(\frac{D}{N} + 1\right) \tag{25.16}$$

Equation (25.16) neglects the presence of daughter atoms, D_0, that may have been present at $t = 0$. To account for this we rewrite equation (25.16) as

$$t = \frac{1}{\lambda}\ln\left(\frac{D_\mathrm{t} - D_0}{N} + 1\right) \tag{25.17}$$

where D_t are the total daughter atoms at the current time. Equation (25.17) cannot be used in its current form to accurately determine the age of geological material. To accurately determine the geological age, we must consider the branching decay. Branching decay occurs when an isotope can decay through different pathways to other nuclides. The figure below illustrates branching for potassium-40. When branching is taken into account, we obtain



$$t = \frac{1}{\lambda_\varepsilon + \lambda_\beta} \ln\left[\frac{^{40}\mathrm{Ar}_{\mathrm{rad}}}{^{40}\mathrm{K}}\left(\frac{\lambda_\varepsilon + \lambda_\beta}{\lambda_\varepsilon} + 1\right)\right] \qquad \mathbf{(25.18)}$$

where λ_ε is the decay constant for the electron capture branch of ^{40}K decay and λ_β is the decay constant for the β-decay branch. $^{40}\mathrm{Ar}_{\mathrm{rad}}$ is the argon-40 produced by the decay of potassium-40 and corrected for the presence of trapped atmospheric argon-40. Several assumptions are made in deriving equation (25.18). The assumption most likely to cause problems is what the source of the argon is in the sample. The argon may be from the potassium-40 decay, it may be atmospheric argon, or it may be a mixture in which it is possible to identify and subtract any atmospheric argon-40 that contaminates the sample.

25-6 Energetics of Nuclear Reactions

The energy change accompanying a nuclear reaction can be described by using the mass–energy equivalence derived by Albert Einstein:

$$E = mc^2 \qquad \mathbf{(25.19)}$$

KEEP IN MIND

that the mass in equation (25.19) is the rest mass of the particle, as discussed on page 305.

An energy change in a process is always accompanied by a mass change, and the constant that relates them is the square of the speed of light. In chemical reactions, energy changes are so small that the equivalent mass changes are undetectable (though real nevertheless). In fact, we base the balancing of equations and stoichiometric calculations on the principle that mass is conserved (unchanged) in a chemical reaction. In nuclear reactions, energies are orders of magnitude greater than in chemical reactions. Perceptible changes in mass do occur.

If the exact masses of atoms are known, the energy of a nuclear reaction can be calculated with equation (25.19). The term m is the net change in mass, in kilograms, and c is expressed in meters per second. The resulting energy is in joules. Another common unit for expressing nuclear energy is the megaelectronvolt (MeV). (Recall from page 1113 that 1 eV $= 1.6022 \times 10^{-19}$ J.)

$$1\ \mathrm{MeV} = 1.6022 \times 10^{-13}\ \mathrm{J} \qquad \mathbf{(25.20)}$$

Equation (25.20) is a conversion factor between megaelectronvolts and joules. A conversion factor between atomic mass units (u) and joules (J) is also helpful. This relationship can be established by determining the energy associated with a mass of 1 u. This calculation is based on carbon-12, and note that 1 u is exactly $\frac{1}{12}$ of the mass of a carbon-12 atom. The mass, in grams, corresponding to 1 u can be calculated as follows:

$$1\ \mathrm{u} \times \frac{1\ ^{12}\mathrm{C\ atom}}{12\ \mathrm{u}} \times \frac{1\ \mathrm{mol}\ ^{12}\mathrm{C}}{6.0221 \times 10^{23}\ \mathrm{atoms}\ ^{12}\mathrm{C}} \times \frac{12\ \mathrm{g}}{1\ \mathrm{mol}\ ^{12}\mathrm{C}} = 1.6606 \times 10^{-24}\ \mathrm{g}$$

Converting this value of m to kilograms and using it in equation (25.19) gives

$$\begin{aligned} E &= 1\ \mathrm{u} \times \frac{1.6606 \times 10^{-24}\ \mathrm{g}}{\mathrm{u}} \times \frac{1\ \mathrm{kg}}{1000\ \mathrm{g}} \times (2.9979 \times 10^8)^2 \frac{\mathrm{m}^2}{\mathrm{s}^2} \\ &= 1.4924 \times 10^{-10}\ \mathrm{J} \end{aligned}$$

Thus, the energy equivalent of 1 u is

$$1\ \text{atomic mass unit (u)} = 1.4924 \times 10^{-10}\ \mathrm{J} \qquad \mathbf{(25.21)}$$

Finally, to express this energy in MeV,

$$1\ \text{atomic mass unit (u)} = 1.4924 \times 10^{-10}\ \mathrm{J} \times \frac{1\ \mathrm{MeV}}{1.6022 \times 10^{-13}\ \mathrm{J}} = 931.5\ \mathrm{MeV} \qquad \mathbf{(25.22)}$$

These conversion factors are used in Example 25-5, together with the principle that the total mass–energy of the products of a nuclear reaction is equal to the total mass–energy of the reactants. The masses required in calculations based on nuclear reactions are *nuclear* masses. The relationship of a nuclear mass to a nuclidic (atomic) mass is

$$\text{nuclear mass} = \text{nuclidic (atomic) mass} - \text{mass of extranuclear electrons}$$

EXAMPLE 25-5 Calculating the Energy of a Nuclear Reaction with the Mass–Energy Relationship

What is the energy, in joules and in megaelectronvolts, associated with the α decay of ^{238}U?

$$^{238}_{92}\text{U} \longrightarrow {}^{234}_{90}\text{Th} + {}^{4}_{2}\text{He}$$

The nuclidic (atomic) masses in atomic mass units (u) are from Table D.5 in Appendix D:

$$^{238}_{92}\text{U} = 238.0508\text{ u} \qquad {}^{234}_{90}\text{Th} = 234.0437\text{ u} \qquad {}^{4}_{2}\text{He} = 4.0026\text{ u}$$

Analyze

The key concept here is the fact that, during a nuclear reaction, a loss or gain of mass is balanced by a gain or loss of energy. We need to determine the loss or gain of mass and then use the conversion factors (25.21) and (25.22) to convert the loss or gain of mass to the corresponding amount of energy.

Solve

The net change in mass that accompanies the decay of a single nucleus of ^{238}U is shown below. Note that the masses of the extranuclear electrons do not enter into the calculation of the net change in mass.

change in mass

$$\begin{aligned}
&= \text{nuclear mass of } {}^{234}_{90}\text{Th} + \text{nuclear mass of } {}^{4}_{2}\text{He} - \text{nuclear mass of } {}^{238}_{92}\text{U} \\
&= [234.0437\text{ u} - (90 \times \text{mass e}^-)] + [4.0026\text{ u} - (2 \times \text{mass e}^-)] - [238.0508\text{ u} - (92 \times \text{mass e}^-)] \\
&= 234.0437\text{ u} + 4.0026\text{ u} - 238.0508\text{ u} - 92 \times \text{mass e}^- + 92 \times \text{mass e}^- \\
&= -0.0045\text{ u}
\end{aligned}$$

We can use this loss of mass and conversion factors (25.21) and (25.22) to write

$$E = -0.0045\text{ u} \times \frac{1.49 \times 10^{-10}\text{ J}}{\text{u}} = -6.7 \times 10^{-13}\text{ J}$$

or

$$E = -0.0045\text{ u} \times \left(\frac{931.5\text{ MeV}}{\text{u}}\right) = -4.2\text{ MeV}$$

Assess

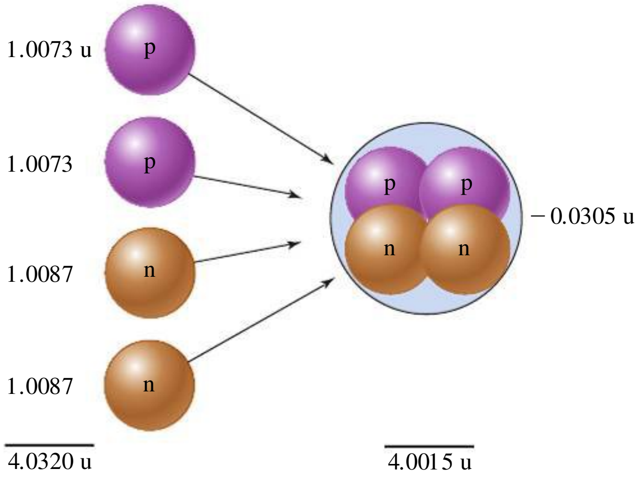
The negative sign denotes that energy is lost in the nuclear reaction. This is the kinetic energy of the departing α particle. Note that you can use either nuclear or nuclidic (atomic) masses in calculations based on a nuclear equation. The change in mass will be the same in either case because the masses of the electrons will cancel out.

PRACTICE EXAMPLE A: What is the energy associated with the α decay of ^{146}Sm (145.913053 u) to ^{142}Nd (141.907719 u)? Use 4.002603 u as the mass of ^{4}He.

PRACTICE EXAMPLE B: The decay of ^{222}Rn by α-particle emission is accompanied by a loss of 5.590 MeV of energy. What quantity of mass, in atomic mass units (u), is converted to energy in this process?

Figure 25-5 suggests formation of the nucleus of a $^{4}_{2}$He atom from two protons and two neutrons. In this process, there is a *mass defect* of 0.0305 u. That is, the experimentally determined mass of a $^{4}_{2}$He nucleus is 0.0305 u *less* than the combined mass of two protons and two neutrons. This "lost" mass is liberated as energy. With expression (25.22), we can show that 0.0305 u of mass is equivalent to an energy of 28.4 MeV. Because this is the energy released in forming a $^{4}_{2}$He nucleus, it is called the **nuclear binding energy**. Viewed another way, a $^{4}_{2}$He nucleus would have to absorb 28.4 MeV to cause its protons and neutrons

▶ Nucleons are nuclear particles: protons and neutrons.



▲ FIGURE 25-5

Nuclear binding energy in $^4_2$He

The mass of a helium nucleus ($^4_2$He) is 0.0305 u (atomic mass unit) less than the combined masses of two protons and two neutrons. The energy equivalent to this loss of mass (called the mass defect) is the nuclear energy that binds the nuclear particles together.

◀ Only four forces are known: gravity, electromagnetic forces, weak nuclear force, and strong nuclear force. The nuclear forces act only within a nucleus, whereas gravity and EM can operate over essentially infinite distances.

to become separated. If the binding energy is considered to be apportioned equally among the two protons and two neutrons in $^4_2$He, the binding energy is 7.10 MeV per nucleon.

Let us calculate the binding energy per nucleon on the following elements: carbon-12, iron-56, and uranium-235. For carbon-12 we first calculate the change in mass:

$$\begin{aligned}\text{change in mass} &= [(6 \times \text{mass } ^1\text{H atom}) + (6 \times \text{mass neutron})] - \text{mass } ^{12}\text{C atom}\\ &= [6 \times 1.007825 \text{ u} + 6 \times 1.008665 \text{ u}] - 12.0000 \text{ u}\\ &= 0.09894 \text{ u}\end{aligned}$$

The mass for the proton and neutron were obtained from Appendix D. The next step is to convert this to the binding energy per nucleon:

$$\text{binding energy per nucleon} = \frac{0.09894 \text{ u} \times \dfrac{931.5 \text{ MeV}}{\text{u}}}{12 \text{ nucleons}} = 7.680 \text{ MeV/nucleon}$$

For iron-56 we find the binding energy per nucleon is

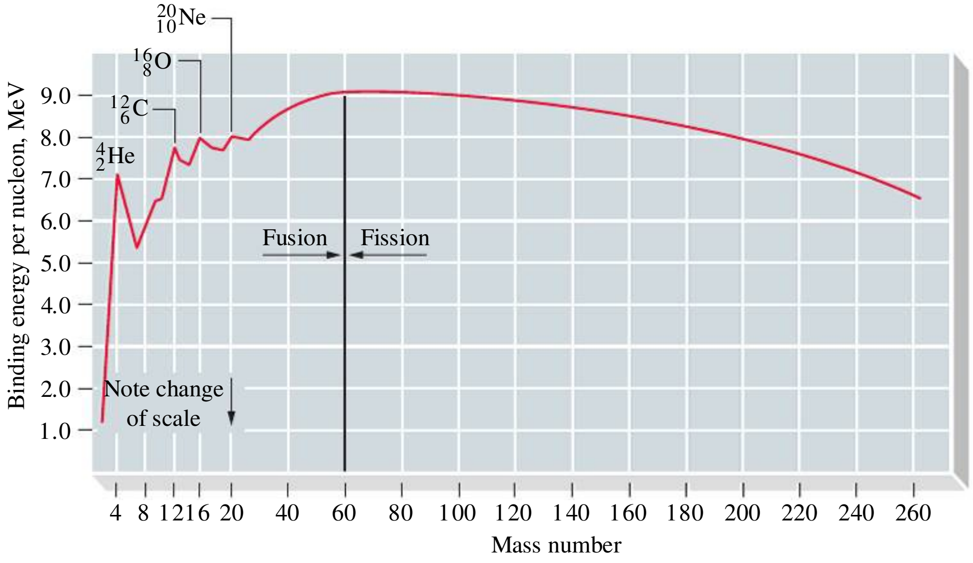
$$\text{binding energy per nucleon} = \frac{0.52846 \text{ u} \times \dfrac{931.5 \text{ MeV}}{\text{u}}}{56 \text{ nucleons}} = 8.790 \text{ MeV/nucleon}$$

and for uranium-235

$$\text{binding energy per nucleon} = \frac{1.921507 \text{ u} \times \dfrac{931.5 \text{ MeV}}{\text{u}}}{235 \text{ nucleons}} = 7.591 \text{ MeV/nucleon}$$

At this point we notice that iron-56 has the larger binding energy per nucleon, meaning that more energy is required to separate the iron-56 nucleons than those of carbon-12 and uranium-235. In other words, iron-56 is more stable than the other two elements.

Figure 25-6 indicates that the maximum binding energy per nucleon is found in a nucleus with a mass number of approximately 60. This finding leads to two interesting conclusions: (1) If small nuclei are combined into a heavier one (up to about $A = 60$), the binding energy per nucleon increases and a



▲ FIGURE 25-6
Average binding energy per nucleon as a function of mass number

certain quantity of mass must be converted to energy. The nuclear reaction is highly exothermic. This *fusion* process serves as the basis of the hydrogen bomb. (2) For nuclei with mass numbers above 60, the addition of extra nucleons to the nucleus would require the expenditure of energy (since the binding energy per nucleon decreases). However, the *disintegration* of heavier nuclei into lighter ones is accompanied by the release of energy. This nuclear *fission* process serves as the basis of the atomic bomb and conventional nuclear power reactors. Nuclear fission and fusion will be discussed after we examine Figure 25-6 and consider the question of nuclear stability.

25-7 Nuclear Stability

A number of basic questions have probably occurred to you as nuclear decay processes have been described: Why do some radioactive nuclei decay by α emission, some by β^- emission, and so on? Why do the lighter elements have so few naturally occurring radioactive nuclides, whereas all those of the heavier elements seem to be radioactive?

Our first clue to answers for such questions comes from Figure 25-6, in which several nuclides are specifically noted. These nuclides have higher binding energies per nucleon than those of their neighbors. Their nuclei are especially stable. This observation is consistent with a theory of nuclear structure known as the *shell theory*. In the formation of a nucleus, protons and neutrons are believed to occupy a series of nuclear shells. This process is analogous to building up the electronic structure of an atom by the successive addition of electrons to electronic shells. Just as the aufbau process periodically produces electron configurations of exceptional stability, so do certain nuclei acquire a special stability as nuclear shells are closed. This condition of special stability of an atomic nucleus occurs for certain numbers of protons or neutrons known as **magic numbers** (Table 25.2).

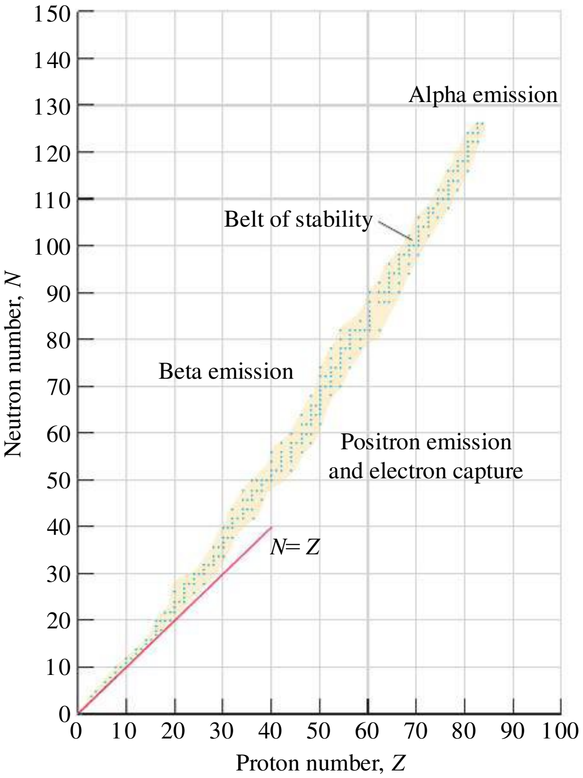
Another observation concerning nuclei is that among stable nuclei, the number of protons and the number of neutrons is most commonly *even*. There are fewer stable nuclei with odd numbers of protons and of neutrons. The relationship between numbers of protons (Z), numbers of neutrons (N), and the stability of isotopes is summarized in Table 25.3. Note particularly that stable atoms with the combination Z odd–N odd are very rare. This combination is found only in the nuclides $^{2}_{1}H$, $^{6}_{3}Li$, $^{10}_{5}B$, and $^{14}_{7}N$. Still another observation is that elements of *odd* atomic number generally have only one or two stable isotopes, whereas those of *even* atomic number have several. Thus, F $(Z = 9)$ and I $(Z = 53)$ each have only one stable nuclide, and Cl $(Z = 17)$ and Cu $(Z = 29)$ each have two. On the other hand, O $(Z = 8)$ has three and Ca $(Z = 20)$ has six.

Neutrons are thought to provide a nuclear force to bind protons and neutrons together into a stable unit. Without neutrons, the electrostatic forces of repulsion between positively charged protons would cause the nucleus to fly apart. For the elements of lower atomic numbers (up to about $Z = 20$), the required number of neutrons for a stable nucleus is about equal to the number of protons, for example, $^{4}_{2}He$, $^{12}_{6}C$, $^{16}_{8}O$, $^{28}_{14}Si$, $^{40}_{20}Ca$. For higher atomic numbers, because of increasing repulsive forces between protons, larger numbers of neutrons are required and the neutron–proton (N/Z) ratio increases. For bismuth, the ratio is about 1.5:1. Above atomic number 83, no matter how many neutrons are present, the nucleus is unstable. Thus, all isotopes of the known elements with $Z > 83$ are radioactive. Figure 25-7 indicates roughly the range of N/Z ratios as a function of atomic number for stable atoms.

Using the ideas outlined here, nuclear scientists have predicted the possible existence of atoms of high atomic number that should have very long half-lives, a belt of stability in Figure 25-7. After a search of many years, such atoms have been created. In 1999, the bombardment of a plutonium-242 target with calcium-48 ions produced the as-yet unnamed isotopes $^{287}114$ and $^{289}114$, with half-lives of 5 s and 30 s, respectively. Although these half-lives may appear short, they are practically an eternity compared with the half-lives of many other superheavy atoms, which are in the microsecond range.

25-4 CONCEPT ASSESSMENT

What proton number is found in a greater number of isotopes than any other proton number? What is the corresponding situation for neutron numbers?



◀ FIGURE 25-7
Neutron-to-proton ratio and the stable nuclides up to $Z = 83$
The points within the belt of stability identify the stable nuclides. Some radioactive nuclides are also in this belt, but most lie outside, and the mode of their radioactive decay is indicated. The stable nuclides of low atomic numbers lie on or near the line $N = Z$; they have a neutron-to-proton ratio of one, or nearly so. At higher atomic numbers, the neutron-to-proton ratios increase to about 1.5.

EXAMPLE 25-6 Predicting Which Nuclei Are Radioactive

Which of the following nuclides would you expect to be stable, and which radioactive? **(a)** ^{82}As; **(b)** ^{118}Sn; **(c)** ^{214}Po.

Analyze

This question requires us to apply the rules of nuclear stability. We may also use Figure 25-7 to determine whether the nuclide lies within the belt of stability.

Solve

(a) Arsenic-82 has $Z = 33$ and $N = 49$. This is an odd–odd combination that is found in only four of the lighter elements. ^{82}As is radioactive. (Note also that this nuclide is outside the belt of stability in Figure 25-7.)

(b) Tin has an atomic number of 50—a magic number. The neutron number is 68 in the nuclide ^{118}Sn. This is an even–even combination, and we should expect the nucleus to be stable. Moreover, Figure 25-7 shows that this nuclide is within the belt of stability. ^{118}Sn is a stable nuclide.

(c) ^{214}Po has an atomic number of 84. All known atoms with $Z > 83$ are radioactive. ^{214}Po is radioactive.

Assess

When considering whether a nuclide is radioactive, we must remember that all elements with $Z > 83$ are radioactive, and those with $Z < 84$ are radioactive if their Z and N form odd–odd combinations. A few exceptions exist to these rules, specifically when nuclides have atomic numbers that are one of the magic numbers.

PRACTICE EXAMPLE A: Which of the following nuclides would you expect to be stable, and which radioactive? **(a)** ^{88}Sr; **(b)** ^{118}Cs; **(c)** ^{30}S.

PRACTICE EXAMPLE B: Write plausible nuclear equations to represent the radioactive decay of the fluorine isotopes ^{17}F and ^{22}F.

25-5 CONCEPT ASSESSMENT

Of the radioactive nuclides among the following, which one is most likely to decay by β^- emission, and which one by β^+ emission: ^{44}Ca, ^{57}Cu, ^{100}Zr, ^{235}U? Explain.

25-8 Nuclear Fission

In 1934, Enrico Fermi proposed that transuranium elements might be produced by bombarding uranium with neutrons. He reasoned that the successive loss of β^- particles would cause the atomic number to increase, perhaps to as high as 96. When such experiments were carried out, it was found that, in fact, the product did emit β^- particles. But in 1938, Otto Hahn, Lise Meitner, and Fritz Strassman found by chemical analysis that the products did not correspond to elements with $Z > 92$. Neither were they the neighboring elements of uranium—Ra, Ac, Th, and Pa. Instead, the products were radioisotopes of much lighter elements, such as Sr and Ba. Neutron bombardment of uranium nuclei causes certain of them to undergo **fission** into smaller fragments, as suggested by Figure 25-8.

▶ Ida Tacke Nodack, codiscoverer of the element rhenium, was the first person to suggest that Fermi's proposed experiments had produced fission. Her explanation was not generally accepted, however, until several years later.

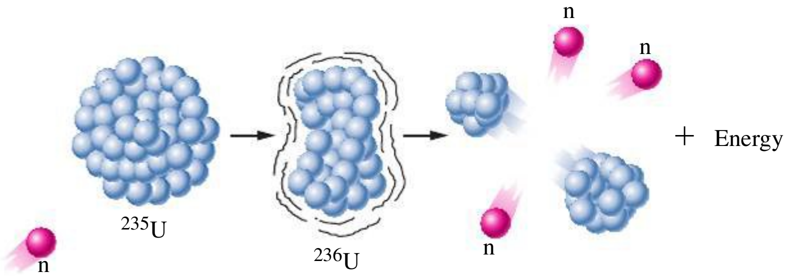
The energy equivalent of the mass destroyed in a fission event is somewhat variable, but the average energy is approximately 3.20×10^{-11} J (200 MeV).

$$^{235}_{92}\text{U} + ^{1}_{0}\text{n} \longrightarrow ^{236}_{92}\text{U} \longrightarrow \text{fission fragments} + \text{neutrons} + 3.20 \times 10^{-11}\ \text{J}$$

An energy of 3.20×10^{-11} J may seem small, but this energy is for the fission of a *single* $^{235}_{92}\text{U}$ nucleus. What if 1.00 g $^{235}_{92}\text{U}$ were to undergo fission?

$$?\ \text{kJ} = 1.00\ \text{g}\ ^{235}\text{U} \times \frac{1\ \text{mol}\ ^{235}\text{U}}{235\ \text{g}\ ^{235}\text{U}} \times \frac{6.022 \times 10^{23}\ \text{atoms}\ ^{235}\text{U}}{1\ \text{mol}\ ^{235}\text{U}} \times \frac{3.20 \times 10^{-11}\ \text{J}}{1\ \text{atoms}\ ^{235}\text{U}}$$

$$= 8.20 \times 10^{10}\ \text{J} = 8.20 \times 10^{7}\ \text{kJ}$$



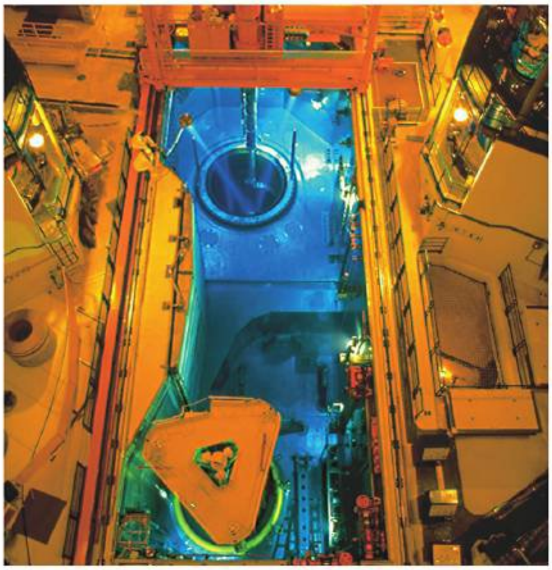
▲ FIGURE 25-8
Nuclear fission of $^{235}_{92}\text{U}$ with thermal neutrons
A neutron possessing ordinary thermal energy strikes a $^{235}_{92}\text{U}$ nucleus. First, the unstable nucleus $^{236}_{92}\text{U}$ is produced; this then breaks up into a light fragment, a heavy fragment, and several neutrons. Various nuclear fragments are possible, but the most probable mass numbers are 97 for the light fragment and 137 for the heavy one.

This is an enormous quantity of energy! To release that quantity of energy would require the complete combustion of nearly three tons of coal.

Nuclear Reactors

In the fission of $^{235}_{92}\text{U}$, on average, 2.5 neutrons are released per fission event. These neutrons, on average, produce two or more fission events. The neutrons produced by the second round of fission produce another four or five events, and so on. The result is a *chain reaction*. If the reaction is uncontrolled, the released energy causes an explosion; this is the basis of the atomic bomb. Fission leading to an uncontrolled explosion occurs only if the quantity of ^{235}U exceeds the critical mass. The *critical mass* is the quantity of ^{235}U sufficiently large to retain enough neutrons to sustain a chain reaction. Quantities smaller than this are subcritical; neutrons escape at too great a rate to produce a chain reaction.

In a nuclear reactor, the release of fission energy is controlled. One common design, called the *pressurized water reactor* (PWR), is pictured in Figure 25-9. In the core of the reactor, rods of uranium-rich fuel are suspended in water maintained under a pressure of 70 to 150 atm. The water serves a dual purpose. First, it slows down the neutrons from the fission process so that they possess only normal thermal energy. These thermal neutrons are better able to induce fission than highly energetic ones. In this capacity, the water acts as a **moderator**. Water



◀ **The core of a nuclear reactor**
The characteristic blue glow in the water surrounding the core is called *Cerenkov radiation*. It results when charged particles pass through a transparent medium faster than does light in the same medium. The charged particles are produced by nuclear fission. The radiation is analogous to the shock wave produced in a sonic boom.

also functions as a heat transfer medium. Fission energy maintains the water at a high temperature (about 300 °C). The high-temperature water is brought in contact with colder water in a heat exchanger. The colder water is converted to steam, which drives a turbine, which in turn drives an electric generator. A final component of the nuclear reactor is a set of **control rods**, usually cadmium

25-2 ARE YOU WONDERING...

About nuclear reactor safety?

There have been two notorious accidents at nuclear power stations. The first occurred at the Three Mile Island (TMI) generating plant near Middleton, Pennsylvania, in 1979. The TMI reactor is of the light-water type, in which water is used as the moderator and coolant. In this accident, some coolant (also the moderator) was lost; the chain reaction in the reactor stopped because there were too few slow neutrons. However, radioactive decay of the fission fragments continued, causing the fuel rods to get very hot. A partial meltdown resulted and, in turn, caused a fracture in one of the reactors. The fracture permitted the venting of a small amount of radioactive steam into the atmosphere. The reactor is now sealed, but electronic robots have discovered substantial damage to the fuel rods.

The second incident occurred at Chernobyl, in the Ukraine, in 1986. Graphite was used as the moderator there. When the coolant was turned off because of human error, the chain reaction went out of control. A tremendous rise in temperature followed, leading to a meltdown. During the meltdown, the graphite moderator surrounding the rods burned and radioactive smoke spewed out of the reactor. Radioactive materials were dispersed over much of Europe, Canada, and the United States. Although only a few dozen people were killed in the Chernobyl accident, many more will eventually die of cancer because of the related radiation. The type of accident observed at Chernobyl cannot happen in a light-water reactor, in which the coolant is the moderator.

Other nations have used nuclear power without experiencing accidents. In France and Japan, two-thirds of the electrical energy is produced by nuclear power stations. The safety record of nuclear reactors is particularly high, but the need for the storage of the nuclear waste produced is a vexing problem. Ways of dealing with these problems are discussed in the Focus On feature for Chapter 25 on the Mastering Chemistry website.

metal, whose function is to absorb neutrons. When the rods are lowered into the reactor, the fission process is slowed down. When the rods are raised, the density of neutrons and the rate of fission increase.

Breeder Reactors

All that is required to initiate the fission of $^{235}_{92}\text{U}$ are neutrons of ordinary thermal energies. Conversely, nuclei of $^{238}_{92}\text{U}$, the abundant nuclide of uranium (99.28%), undergo the following reactions only when struck by energetic neutrons.

$$
\begin{aligned}
^{238}_{92}\text{U} + {}^{1}_{0}\text{n} &\longrightarrow {}^{239}_{92}\text{U} \\
^{239}_{92}\text{U} &\longrightarrow {}^{239}_{93}\text{Np} + {}^{0}_{-1}\beta \\
^{239}_{93}\text{Np} &\longrightarrow {}^{239}_{94}\text{Pu} + {}^{0}_{-1}\beta
\end{aligned}
$$

A fissionable nuclide such as $^{235}_{92}\text{U}$ is called *fissile*; $^{239}_{94}\text{Pu}$ is also fissile. A nuclide such as $^{238}_{92}\text{U}$, which can be converted into a fissile nuclide, is said to be *fertile*. In a *breeder nuclear reactor*, a small quantity of fissile nuclide provides the neutrons that convert a large quantity of a fertile nuclide into a fissile one. (The newly formed fissile nuclide then participates in a self-sustaining chain reaction.)

An obvious advantage of the breeder reactor is that the amount of uranium fuel available immediately jumps by a factor of about 100. This is the ratio of naturally occurring $^{238}_{92}\text{U}$ to $^{235}_{92}\text{U}$. But the potential advantage is even greater than this. Breeder reactors might use as nuclear fuels materials that have even very low uranium contents, such as shale deposits with about 0.006% U by mass.

There are, however, important disadvantages to breeder reactors. This is especially true of the type known as the *liquid-metal-cooled fast breeder reactor* (LMFBR). Systems must be designed to handle a liquid metal, such as sodium, which becomes highly radioactive in the reactor. Also, both the rates of heat and neutron production are greater in the LMFBR than in the PWR, so materials deteriorate more rapidly. Perhaps the greatest unsolved problems are those of handling radioactive wastes and reprocessing plutonium fuel. Plutonium is one of the most toxic substances known. It can cause lung cancer when inhaled in even microgram (10^{-6} g) amounts. Furthermore, because plutonium has a long half-life (24,000 y), any accident involving it could leave an affected area almost permanently contaminated.

25-9 Nuclear Fusion

The **fusion** of atomic nuclei is the process that produces energy in the sun. An uncontrolled fusion reaction is the basis of the hydrogen bomb. A controlled fusion reaction could provide an almost unlimited source of energy. The nuclear reaction that holds the most immediate promise is the deuterium–tritium reaction.

$$^{2}_{1}\text{H} + {}^{3}_{1}\text{H} \longrightarrow {}^{4}_{2}\text{He} + {}^{1}_{0}\text{n} + \text{energy}$$

The difficulties in developing a fusion energy source are probably without parallel in the history of technology. In fact, the feasibility of a controlled fusion reaction has yet to be fully demonstrated. There are a number of problems. To permit their fusion, the nuclei of deuterium and tritium must be forced into close proximity. Because atomic nuclei repel one another, this close approach requires the nuclei to have very high thermal energies. At the temperatures necessary to initiate a fusion reaction, gases are completely ionized into a mixture of atomic nuclei and electrons known as a *plasma*. Still higher plasma temperatures—more than 40,000,000 K—are required to initiate a self-sustaining reaction (one that releases more energy than is required to get it started). A method must be devised to confine the plasma out of contact with other materials. The plasma loses thermal energy to any material it strikes. Also, a plasma must be at a sufficiently high density for a sufficient time to

◀ In the hydrogen bomb, these high temperatures are attained by exploding an atomic (fission) bomb, which triggers the fusion reaction.

KEEP IN MIND

that *both* nuclear fusion and nuclear fission reactions release energy.

permit the fusion reaction to occur. The two methods receiving greatest attention are confinement in a magnetic field and heating of a frozen deuterium-tritium pellet with laser beams. Another series of technical problems involves the handling of liquid lithium, which is the anticipated heat-transfer medium and tritium ($^{3}_{1}H$) source.

$$^{7}_{3}\text{Li} + \underset{\text{(fast)}}{^{1}_{0}\text{n}} \longrightarrow {}^{4}_{2}\text{He} + {}^{3}_{1}\text{H} + \underset{\text{(slow)}}{^{1}_{0}\text{n}}$$

Finally, for the magnetic containment method, the magnetic field must be produced by superconducting magnets, which currently are very expensive to operate.

▲ The plasma chamber of a fusion reactor of the magnetic confinement type (called a *tokamak*). The chamber walls are lined with carbon-fiber composite tiles to protect against the high-temperature plasma.

A fusion reactor is currently being developed in France by an international consortium consisting of the European Union (EU), India, Japan, People's Republic of China, Russia, South Korea, the United States, and Portugal. The project, titled ITER (International Thermonuclear Experimental Reactor), is based on the tokamak design shown in the photo in the margin. The goal of the project is to generate and sustain 500 MW of fusion power for 1000 seconds through the fusion of 0.5 g of a deuterium–tritium mixture. ITER is expected to generate 5 to 10 times as much energy as is needed to initiate the reaction at its fusion temperature. The first operation of the fusion reactor should take place in 2018.

The advantages of fusion over fission could be enormous. Since deuterium constitutes about one in every 6500 H atoms, the oceans of the world can supply an almost limitless amount of nuclear fuel. It is estimated that there is sufficient lithium on Earth to provide a source of tritium for about 1 million years. Also, nuclear fusion would not pose the vexing problems of radioactive waste storage and disposal associated with nuclear fission.

25-10 Effect of Radiation on Matter

Although there are substantial differences in the way in which α particles, β^{-} and β^{+} particles, and γ rays interact with matter, they share an important feature: They dislodge electrons from atoms and molecules to produce ions. The ionizing power of radiation may be described in terms of the number of ion pairs formed per centimeter of path through a material. An *ion pair* consists of an ionized electron and the resulting positive ion. Alpha particles have the greatest ionizing power, followed by β particles and then γ rays. The ionized electrons produced directly by the collisions of particles of radiation with atoms are called *primary* electrons. These electrons may themselves possess sufficient energies to cause *secondary* ionizations.

Not all interactions between radiation and matter produce ion pairs. In some cases, electrons are simply raised to higher atomic or molecular energy levels. The return of these electrons to their normal states is then accompanied by radiation—X rays, ultraviolet light, or visible light, depending on the energies involved.

Some of the possibilities described here are depicted in Figure 25-10.

Radiation Detectors

The interactions of radiation with matter can serve as bases for the detection of radiation and the measurement of its intensity. One of the simplest methods is that used by Henri Becquerel in his discovery of radioactivity—the exposure of a photographic film, as in film badge radiation detectors. The effect of α and β particles, and γ rays on a photographic emulsion is similar to that of X rays.

One type of detector used to study high-energy radiation such as γ rays is the *bubble chamber*. In this device, a liquid, usually hydrogen, is kept just at its boiling point. As ion pairs are produced by the transit of an ionizing ray,

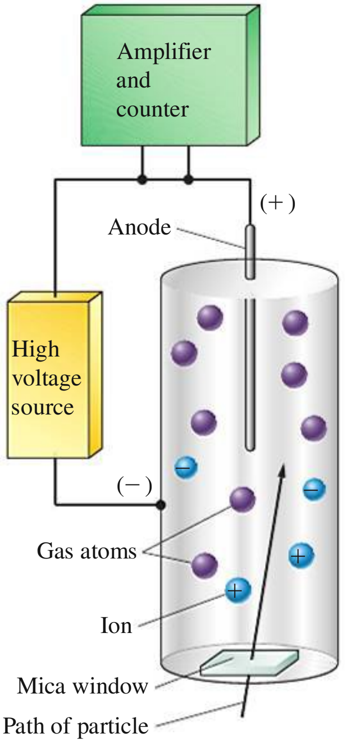
bubbles of vapor form around the ions. The tracks of bubbles can be photographed and analyzed, and different types of radiation produce different tracks. Charged particles, for example, can be detected by their deflection in a magnetic field.

The most common device for detecting and measuring ionizing radiation is the *Geiger–Müller* (G–M) *counter*, depicted in Figure 25-11. The G–M counter consists of a cylindrical cathode with a wire anode running along its axis. The anode and cathode are sealed in a gas-filled glass tube. Ionizing radiation passing through the tube produces primary ions, and this is followed by secondary ionization. The positive ions are attracted to the cathode and the electrons to the anode, leading to a pulse of electric current. The tube is quickly recharged in preparation of the next ionizing event. The pulses of electric current are counted.

A detector widely used in biological studies is the *scintillation counter*. It is especially useful in detecting radiation that is not energetic enough to cause ionization. The radiation excites certain atoms in the detecting medium; when these atoms revert to their ground state, they emit pulses of light that can be counted. The light emission is similar to that produced when phosphors in a television screen are struck by cathode rays.



▲ FIGURE 25-11

Radiation enters the G–M tube through the mica window. The radiation ionizes some of the gas (usually argon) in the tube. A pulse of electric current passes through the electric circuit and is counted.

Effect of Ionizing Radiation on Living Matter

All life exists against a background of naturally occurring ionizing radiation—cosmic rays, ultraviolet light, and emanations from radioactive elements, such as uranium in rocks. The level of this radiation varies from point to point on Earth, being greater, for instance, at higher elevations. Only in recent times have humans been able to create situations in which organisms might be exposed to radiation at levels significantly higher than natural background radiation.

The interactions of radiation with living matter are the same as with other forms of matter—ionization, excitation, and dissociation of molecules. There is no question of the effect of large doses of ionizing radiation on organisms—the organisms are killed. But even slight exposures to ionizing radiation can cause changes in cell chromosomes. Thus it is believed that, even at low dosage rates, ionizing radiation can result in birth defects, leukemia, bone cancer, and other forms of cancer. The nagging question that has eluded any definitive answers is how great an increase in the incidence of birth defects and cancers might be caused by certain levels of radiation.

▲ Laboratory technician checking for radioactive isotopes.

Radiation Dosage

One unit long used to describe exposure to radiation is the rad. One **rad** (*r*adiation *a*bsorbed *d*ose) corresponds to the absorption of 1×10^{-2} J of energy per kilogram of matter. The effect of a dose of one rad on living matter is variable, however, and a better unit is one that takes this variability into account. The **rem** (*r*adiation *e*quivalent for *m*an) is the rad multiplied by the *relative biological effectiveness* (Q). The factor Q takes into account that equal doses of radiation of different types may have differing effects. Table 25.4 summarizes several radiation units.

It is thought that a dose of 1000 rem absorbed in a short time interval will kill 100% of the population. A short-term dose of 450 rem would probably result in death within 30 days of about 50% of the population. A single dose of 1 rem delivered to 1 million people would probably produce about 100 cases of cancer within 20–30 years. The total body radiation received by most of the world's population from normal background sources is about 0.13 rem [130 millirem (mrem)] per year. The dose delivered in a chest X-ray examination is about 20 mrem.

Some of the foregoing statements about radiation dosages and their anticipated effects are based on (1) medical histories of the survivors of the Hiroshima and Nagasaki atomic blasts, (2) the incidence of leukemia and other cancers in children whose mothers received diagnostic radiation during pregnancy, and (3) the occurrence of lung cancers among uranium miners in the United States. What does all of this tell us about a safe level of radiation exposure? One approach has been to extrapolate from these high doses to the lower doses affecting the general population. This has led the U.S. National Council on Radiation Protection and Measurements to recommend that the dosage for the general population be limited to 0.17 rem (170 mrem) per year from all sources above background level. Experts disagree, however, on how the data observed for high dosages should be extrapolated to low doses. Some experts believe that the 0.17 rem/y figure is too high. If they are right,

TABLE 25.4 Radiation Units[a]

Unit	Definition
Radioactive decay:	
Becquerel, Bq	s^{-1} (disintegrations per second)
Curie, Ci	An amount of radioactive material decaying at the same rate as 1 g of radium (3.70×10^{10} dis s^{-1}) 1 Ci = 3.70×10^{10} Bq
Absorbed dose:	
Gray, Gy	One gray of radiation deposits one joule of energy per kilogram of matter
Rad	1 rad = 0.01 Gy
Equivalent dose:	
Sievert, Sv	1 Sv = 100 rem
Rem	1 rem = 1 rad × Q The quality factor, Q, is about 1 for X rays, γ rays, and β^- particles; 3 for slow neutrons; 10 for protons and fast neutrons; and 20 for α particles

[a] SI units are shown in blue. Sources of α radiation are relatively harmless when external to the body and extremely hazardous when taken internally, as in the lungs or stomach. Other forms of radiation (X rays, γ rays), because they are highly penetrating, are hazardous even when external to the body.

an additional dosage of 0.17 rem/y above normal background levels might cause statistically significant increases in the incidence of birth defects and cancers.

An Environmental Issue Involving Radon

All atoms with an atomic number greater than 83 are radioactive. The nuclei of these atoms are unstable and emit α, β, and γ radiation, eventually breaking down to more stable elements with lower atomic numbers. Radon-222, a colorless, odorless gas, is produced by the loss of α particles from radium-226, which in turn results from the radioactive decay, through several steps, of uranium-238.

In December 1984, a worker at a nuclear power plant in New Jersey registered high readings on a radiation detector during a routine safety check. But the radiation he had been exposed to didn't come from within the plant—it came from his own home. This incident led to the recognition that people can be exposed to high levels of radioactivity from radon. An estimated 21,000 lung cancer deaths per year are attributable to residential radon exposure. It is also estimated that 7 million homes have radon limits in excess of the U.S. Environmental Protection Agency's reference level of 150 Bq m^{-3}. The possible harmful effects of this exposure, primarily an increased risk of lung cancer, are fairly well documented, but the topic remains one of continuing research and debate.

In some instances, the source of radon is in wastes from uranium mining or phosphate production. In most cases, it is emitted by the radioactive decay of ^{238}U present in small amounts in rocks and soils. Because radon is a gas, it readily passes through air passages in the body and is breathed in and out. The product formed when a ^{222}Rn atom gives up an α particle is the isotope polonium-218, which also emits α particles. Unlike radon, polonium is a solid. Health hazards posed by radon seem to be from ^{218}Po and other radioactive decay products becoming attached to dust particles in the air and then being breathed into the lungs.

Fortunately, indoor radon can be rather easily detected because of its radioactivity. The chief method of reducing radon levels is through improved ventilation and by venting subsoil radon to keep it from concentrating within a building. Minimizing indoor radon should be a part of building construction.

25-11 Applications of Radioisotopes

We have described both the destructive capacity of nuclear reactions and the potential of these reactions to provide new sources of energy. Less heralded but equally important are a variety of practical applications of radioactivity. We close this chapter with a brief survey of some uses of radioisotopes.

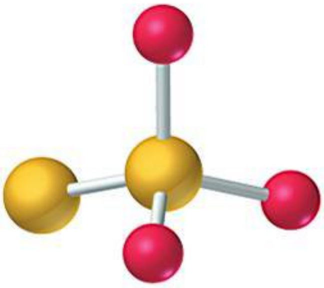
Cancer Therapy

Ionizing radiation in low doses can induce cancers, but this same radiation, particularly γ rays, is also used in the treatment of cancer. Although ionizing radiation tends to destroy all cells, cancerous cells are more easily destroyed than normal ones. Thus, a carefully directed beam of γ rays or high-energy X rays of the appropriate dosage may be used to arrest the growth of cancerous cells. Also coming into use for some forms of cancer is radiation therapy that employs beams of protons or neutrons.

Radioactive Tracers

The small mass differences between the isotopes of an element may produce small differences in physical properties. The differing rates of diffusion of $^{238}UF_6(g)$ and $^{235}UF_6(g)$ result from such a mass difference (page 224). Generally speaking, though, the physical and chemical properties of the various isotopes of an element are practically identical. However, if one of the isotopes is radioactive, its actions can be easily followed with radiation detectors. This is the principle behind the use of *radioactive tracers*, or tagged atoms. For example, if a small quantity of radioactive ^{32}P (as a phosphate) is added to a nutrient solution fed to plants, the uptake of all the phosphorus atoms—radioactive and nonradioactive alike—can be followed by charting the regions of the plant that become radioactive. Similarly, the fate of iodine (as iodide ion) in the body can be determined by having a person drink a solution of dissolved iodides containing a small quantity of a radioactive iodide as a tracer. Abnormalities in the thyroid gland can be detected in this way. Because I^- concentrates in the thyroid, people can protect themselves by ingesting nonradioactive iodides before being exposed to a radioactive iodide. The thyroid becomes saturated with the nonradioactive iodide and rejects the radioactive iodide. Iodide tablets were distributed to the general population in some regions of Europe before the arrival of fallout from the Chernobyl nuclear accident in 1986.

Industrial applications of tracers are also numerous. The fate of a catalyst in a chemical plant can be followed by incorporating a radioactive tracer in the catalyst, such as ^{192}Ir in a Pt-Ir catalyst. Monitoring the activity of the ^{192}Ir makes it possible to determine the rate at which the catalyst is being carried away and to which parts of the plant it is being carried.



▲ FIGURE 25-12
Structure of thiosulfate ion, $S_2O_3{}^{2-}$
The central S atom is in the +6 oxidation state. The terminal S atom is in the −2 oxidation state.

Structures and Mechanisms

Often the mechanism of a chemical reaction or the structure of a species can be inferred from experiments using radioisotopes as tracers. Consider the following experimental proof that the two S atoms in the thiosulfate ion, $S_2O_3{}^{2-}$, are not equivalent.

$S_2O_3{}^{2-}$ is prepared from radioactive sulfur (^{35}S) and sulfite ion containing the nonradioactive isotope ^{32}S.

$$^{35}S + {}^{32}SO_3{}^{2-} \longrightarrow {}^{35}S^{32}SO_3{}^{2-} \qquad (25.23)$$

When the thiosulfate ion is decomposed by acidification, all the radioactivity appears in the precipitated sulfur and none in the $SO_2(g)$. The bonds of the ^{35}S atoms must be different from those of the ^{32}S atoms (Fig. 25-12).

$$^{35}S^{32}SO_3{}^{2-} + 2\,H^+ \longrightarrow H_2O + {}^{32}SO_2(g) + {}^{35}S(s) \qquad (25.24)$$

In reaction (25.25), nonradioactive KIO_4 is added to a solution containing iodide ion labeled with the radioisotope ^{128}I. All the radioactivity appears in the I_2 and none in the $IO_3{}^-$. This proves that all the $IO_3{}^-$ is produced by reduction of $IO_4{}^-$ and none by oxidation of I^-.

$$IO_4{}^- + 2\,{}^{128}I^- + H_2O \longrightarrow {}^{128}I_2 + IO_3{}^- + 2\,OH^- \qquad (25.25)$$

▲ Neutron activation was used to establish that this painting was not painted by Rembrandt, but by an artist in the school of Rembrandt.

Analytical Chemistry

The usual procedure of analyzing a substance by precipitation involves filtering, washing, drying, and weighing a pure precipitate. An alternative is to incorporate a radioactive isotope in the precipitating reagent. By measuring the activity of the precipitate and comparing it with that of the original solution, the amount of precipitate can be calculated without having to purify, dry, and weigh it.

Another method of importance in analytical chemistry is *neutron activation analysis*. In this procedure, the sample to be analyzed, normally nonradioactive, is bombarded with neutrons; the element of interest is converted to a radioisotope. The conversion of a stable isotope (X) to an unstable isotope (X*) by neutron capture can be represented as

$$^{A}X + {}^{1}_{0}n \longrightarrow {}^{(A+1)}X^* \longrightarrow {}^{(A+1)}X + \gamma$$

In this example, the excited nucleus that is formed decays with the emission of a γ ray with a distinctive energy. Neutron-activated nuclei may decay by other modes, however, such as β decay. The activity of the radioisotope formed is measured. This measurement, together with such factors as the rate of neutron bombardment, the half-life of the radioisotope, and the efficiency of the radiation detector, can be used to calculate the quantity of the element in the sample. The method is especially attractive because (1) trace quantities of elements can be determined (sometimes in parts per billion or less); (2) a sample can be tested without destroying it; and (3) the sample can be in any state of matter, including biological materials. Neutron activation analysis has been used, for instance, to determine the authenticity of old paintings. Old masters formulated their own paints. Differences between formulations are easily detected through the trace elements they contain.

Radiation Processing

Radiation processing describes industrial applications of ionizing radiation—γ rays from ^{60}Co or electron beams from electron accelerators. The ionizing radiation is used in the production of certain materials or to modify their properties. Its most extensive current use is in breaking, re-forming, and cross-linking polymer chains to affect the physical and mechanical properties of plastics used in foamed products, electrical insulation, and packaging materials. Ionizing radiation is used to sterilize medical supplies, such as sutures, syringes, and hospital garb. In sewage treatment plants, radiation processing has been used to decrease the settling time of sewage sludge and to kill pathogens. Radiation is now being used in some instances in the preservation of foods as an alternative to canning, freeze-drying, or refrigeration. In radiation processing, the irradiated material is not rendered radioactive, although the ionizing radiation may produce some chemical changes.

MasteringCHEMISTRY **www.masteringchemistry.com**

The use of nuclear reactions is an attractive "clean" approach to meeting today's energy consumption. However, the waste products created by nuclear power plants are not easily disposed. For a discussion of different methods of handling nuclear waste, go to the Focus On feature for Chapter 25, Radioactive Waste Disposal, on the Mastering Chemistry site.

Summary

25-1 Radioactivity—All the heavier elements ($Z > 83$) and a few of the lighter ones have naturally occurring nuclides that produce ionizing radiation. **Alpha (α) particles** emanating from radioactive nuclei are identical to the nuclei of helium-4 atoms, $^4_2He^{2+}$. **Beta (β^-) particles** are electrons that originate from the conversion of a neutron to a proton in the radioactive nucleus; **positrons (β^+)** are positively charged particles otherwise identical to electrons that originate in the nucleus in the conversion of a proton to a neutron. Beta ($-$) particles and positrons have a greater penetrating power through matter than do α particles. **Electron capture (EC)** occurs when an electron from a low-lying energy level is absorbed by the nucleus. The electron and a proton combine to form a neutron and liberate X radiation. **Gamma (γ)** rays are a nonparticulate form of electromagnetic radiation released when a nucleus in an excited state returns to the ground state. **Nuclear equations** to represent nuclear processes must be balanced, which requires that (1) the sum of the mass numbers and (2) the sum of the atomic numbers must be the same on both sides of the nuclear equation (equation 25.1).

25-2 Naturally Occurring Radioactive Isotopes—All naturally occurring radioactive nuclides of high atomic number are members of a **radioactive decay series** that originates with a long-lived isotope of high atomic number and terminates with a stable isotope, such as ^{206}Pb (Fig. 25-2).

25-3 Nuclear Reactions and Artificially Induced Radioactivity—Radioactive nuclides can be synthesized by nuclear reactions in which target nuclei are bombarded with energetic particles such as α particles or neutrons. More than 1000 radioactive nuclides have been produced in this way. Many of them have important practical applications.

25-4 Transuranium Elements—Elements beyond $Z = 92$, commonly referred to as the transuranium elements, have been synthesized by bombarding naturally occurring isotopes with charged particles produced in a charged-particle accelerator (Fig. 25-3).

25-5 Rate of Radioactive Decay—The **radioactive decay law**, based on experimental observations, states that the decay rate is directly proportional to the number of atoms present; hence it is a first-order process (equation 25.11). The proportionality constant between the decay rate and the number of atoms is the **decay constant**, λ. The **half-life**, $t_{1/2}$, is the time it takes for half of the radioactive atoms in a sample to decay. Important applications of the radioactive decay law are radiocarbon dating to determine the age of materials derived from once-living matter and determining the age of rocks and of Earth itself.

25-6 Energetics of Nuclear Reactions—The energy changes in nuclear reactions are a consequence of Einstein's discovery of a mass–energy equivalence (equation 25.19). **Nuclear binding energy** is the energy released when nucleons fuse together into a nucleus; the "lost" mass is known as the mass defect. A plot of binding energy per nucleon versus mass number passes through a maximum at about $A = 60$. Thus, the *fusion* of nucleons is favored at lower mass numbers, and the *fission* of nuclei into lighter fragments is favored at higher mass numbers (Fig. 25-6).

25-7 Nuclear Stability—The stability of a nuclide depends on the ratio N/Z, on whether the numbers of neutrons (N) and protons (Z) are odd or even, and whether either is a **magic number** arising from nuclear shell theory (Table 25.2). A plot of N versus Z shows that all stable nuclides lie within a belt of stability originating along the line $N = Z$, and expanding above the line at higher values of Z (Figure 25-7). Most radioactive nuclides lie outside the belt and undergo radioactive decay of a type that moves daughter nuclides into the belt.

25-8 Nuclear Fission—In the process of **fission**, the nucleus of a heavy nuclide, such as ^{235}U, splits into two smaller fragments after being struck by a thermal neutron (Fig. 25-8). Also released are two or three neutrons that can trigger the fission of other nuclei in a chain reaction. Essential components of a nuclear power reactor (Fig. 25-9) are the fissionable (*fissile*) nuclide, a **moderator** (such as water) to slow down the neutrons released during fission, **control rods** (such as cadmium) to control the fission by absorbing neutrons, and a heat-transfer medium (such as water).

25-9 Nuclear Fusion—The **fusion** of lighter nuclei into heavier ones converts small quantities of mass into enormous amounts of energy. This process occurs continuously in stars and in the hydrogen bomb. A controlled fusion reaction has yet to be achieved, but fusion research is being actively pursued because of the enormous potential of fusion as an energy source.

25-10 Effect of Radiation on Matter—The ionizing power of radiation (Fig. 25-10) is the basis both of radiation's effects on matter and methods used to detect radiation. Radiation detectors include simple film badges, Geiger–Müller (G–M) counters for routine measurements (Fig. 25-11), and scintillation counters in biomedical studies. Two units of measure are used to quantify exposure to radioactivity. One—the **rad** (radiation absorbed dose)—is related to the amount of radiation energy absorbed, while the other—the **rem** (radiation equivalent for man)—takes into account the differing effects of the various types of radiation (Table 25.4).

25-11 Applications of Radioisotopes—Radioactive nuclides have important uses in diagnostic medicine, in cancer therapy, in studying the mechanisms of chemical and biochemical reactions, and as tracers in various scientific and industrial settings. Additionally, radiation processing is used in processing and preserving food.

Integrative Example

On April 26, 1986, an explosion at the nuclear power plant at Chernobyl, Ukraine, released the greatest quantity of radioactive material ever associated with an industrial accident. (See the discussion and photo on pages 1131–1132.) One of the radioisotopes in this emission was ^{131}I, a β^- emitter with a half-life of 8.04 days.

Assume that the total quantity of ^{131}I released was 250 g, and determine the number of *curies* associated with this ^{131}I 30.0 days after the accident.

Analyze

From the initial mass of ^{131}I and the known half-life of ^{131}I determine how many grams of ^{131}I remain after 30 days. Convert this mass to a number of atoms using the molar mass of ^{131}I and Avogadro's number. Finally, the product of the number of atoms and the decay constant yields the activity in disintegrations per second, which can be converted to curies.

Solve

In equation (25.12), use $\lambda = 0.693/8.04\text{ d}$ and $t = 30.0\text{ d}$. Because the mass of ^{131}I is directly proportional to the number of ^{131}I atoms, we can replace N_0 by $mass_0 = 250\text{ g}$, and N_t by $mass_t$, the mass we seek.

$$\ln\frac{mass_t}{mass_0} = \ln\frac{mass_t}{250\text{ g}} = \frac{-0.693}{8.04\text{ d}} \times 30.0\text{ d} = -2.59$$

$$mass_t = 250\text{ g} \times e^{-2.59} = 250\text{ g} \times 0.0750 = 18.8\text{ g}$$

To determine the number of iodine-131 atoms, use the molar mass, $131\text{ g } ^{131}I/\text{mol } ^{131}I$, and the Avogadro constant.

$$N_t = 18.8\text{ g } ^{131}I \times \frac{1\text{ mol } ^{131}I}{131\text{ g } ^{131}I} \times \frac{6.022 \times 10^{23}\ ^{131}I\text{ atoms}}{1\text{ mol } ^{131}I}$$

$$= 8.64 \times 10^{22}\ ^{131}I\text{ atoms}$$

To establish the decay constant in s^{-1} and to obtain λ from $t_{1/2}$, use the method outlined in Example 25-3a.

$$\lambda = 0.693/t_{1/2} = \frac{0.693}{8.04\ \text{d}} \times \frac{1\ \text{d}}{24\ \text{h}} \times \frac{1\ \text{h}}{60\ \text{min}} \times \frac{1\ \text{min}}{60\ \text{s}}$$
$$= 9.98 \times 10^{-7}\ \text{s}^{-1}$$

To determine the decay rate (activity) after 30.0 days, use the two previous results in equation (25.11).

$$A = \lambda N = 9.98 \times 10^{-7}\ \text{s}^{-1} \times 8.64 \times 10^{22}\ \text{atoms}$$
$$= 8.62 \times 10^{16}\ \text{dis s}^{-1}$$

Finally, to express the activity in curies use the definition of a curie given in Table 25.4.

$$A = 8.62 \times 10^{16}\ \text{dis s}^{-1} \times \frac{1\ \text{Ci}}{3.70 \times 10^{10}\ \text{dis s}^{-1}}$$
$$= 2.33 \times 10^{6}\ \text{Ci}$$

Assess

In this calculation we could also have shown that in 30 days (about $4 \times t_{1/2}$) approximately 93% of the ^{131}I had disintegrated. In the process, approximately 2×10^{6} Ci of radiation was emitted. If we also knew the energy of the β^- particles and something about the exposed population, we could also have estimated radiation doses in rads.

PRACTICE EXAMPLE A: ^{40}K undergoes radioactive decay by electron capture to ^{40}Ar and by β^- emission to ^{40}Ca. The fraction of the decay that occurs by electron capture is 0.110. The half-life of ^{40}K is 1.25×10^{9} years. Assuming that a rock in which ^{40}K has undergone decay retains all the ^{40}Ar produced, what would be the $^{40}Ar/^{40}K$ mass ratio in a rock that is 1.5×10^{9} years old?

PRACTICE EXAMPLE B: Most nuclear power plants use zirconium in the fuel rods because zirconium maintains its structural integrity under exposure to the radiation in the nuclear reactor. The nuclear accidents at both Three Mile Island and Chernobyl involved the evolution of hydrogen gas from the reduction of water. The half-cell reduction potential for Zr is

$$ZrO_2(s) + 4\,H_3O^+(aq) + 4\,e^- \longrightarrow Zr(s) + 6\,H_2O(l) \qquad E^\circ = -1.43\ \text{V}$$

(a) Can Zr reduce water under standard-state conditions?
(b) Calculate the equilibrium constant for the reduction of water by zirconium.
(c) Is the reaction spontaneous if the pH = 7 and Zr, ZrO_2, and water are in their standard states?
(d) Was the reduction of water by Zr the culprit in the reactor accidents mentioned above?

MasteringCHEMISTRY

You'll find a link to additional self study questions in the study area on www.masteringchemistry.com

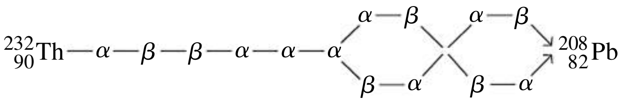
Exercises

Radioactive Processes

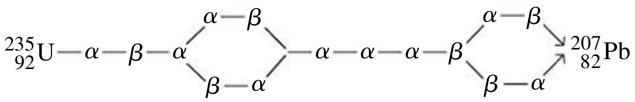
1. What nucleus is obtained in each process?
   (a) $^{234}_{94}Pu$ decays by α emission.
   (b) $^{248}_{97}Bk$ decays by β^- emission.
   (c) $^{196}_{82}Pb$ goes through two successive EC processes.
2. What nucleus is obtained in each process?
   (a) $^{214}_{82}Pb$ decays through two successive β^- emissions.
   (b) $^{226}_{88}Ra$ decays through three successive α emissions.
   (c) $^{69}_{33}As$ decays by β^+ emission.
3. Based on a favorable $N-Z$ ratio for the product nucleus, write the most plausible equation for the decay of $^{14}_{6}C$.
4. Write a plausible equation for the decay of tritium, $^{3}_{1}H$, the radioactive isotope of hydrogen.

Radioactive Decay Series

5. The natural decay series starting with the radionuclide ${}^{232}_{90}\text{Th}$ follows the sequence represented here. Construct a graph of this series, similar to Figure 25-2.



6. The natural decay series starting with the radionuclide ${}^{235}_{92}\text{U}$ follows the sequence represented here. Construct a graph of this series, similar to Figure 25-2.



7. The uranium series described in Figure 25-2 is also known as the "$4n + 2$" series because the mass number of each nuclide in the series can be expressed by the equation $A = 4n + 2$, where n is an integer. Show that this equation is indeed applicable to the uranium series.

8. Just as the uranium series is called the "$4n + 2$" series, the thorium series can be called the "4n" series and the actinium series the "$4n + 3$" series. A "$4n + 1$" series has also been established, with ${}^{241}_{94}\text{Pu}$ as the parent nuclide. To which series does each of the following belong: **(a)** ${}^{214}_{83}\text{Bi}$; **(b)** ${}^{216}_{84}\text{Po}$; **(c)** ${}^{215}_{85}\text{At}$; **(d)** ${}^{235}_{92}\text{U}$?

Nuclear Reactions

9. Supply the missing information in each of the following nuclear equations representing a radioactive decay process.

(a) ${}^{160}_{?}\text{W} \longrightarrow {}^{?}_{?}\text{Hf} + ?$

(b) ${}^{38}_{?}\text{Cl} \longrightarrow {}^{?}_{?}\text{Ar} + ?$

(c) ${}^{214}_{?}? \longrightarrow {}^{?}_{?}\text{Po} + {}^{0}_{-1}\beta$

(d) ${}^{32}_{17}\text{Cl} \longrightarrow {}^{?}_{16}? + ?$

10. Complete the following nuclear equations.

(a) ${}^{23}_{11}\text{Na} + ? \longrightarrow {}^{24}_{11}\text{Na} + {}^{1}_{1}\text{H}$

(b) ${}^{59}_{27}\text{Co} + {}^{1}_{0}\text{n} \longrightarrow {}^{56}_{25}\text{Mn} + ?$

(c) $? + {}^{2}_{1}\text{H} \longrightarrow {}^{240}_{94}\text{Pu} + {}^{0}_{-1}\beta$

(d) ${}^{246}_{96}\text{Cm} + ? \longrightarrow {}^{254}_{102}\text{No} + 5\,{}^{1}_{0}\text{n}$

(e) ${}^{238}_{92}\text{U} + ? \longrightarrow {}^{246}_{99}\text{Es} + 6\,{}^{1}_{0}\text{n}$

11. Write equations for the following nuclear reactions.

(a) bombardment of ${}^{7}\text{Li}$ with protons to produce ${}^{8}\text{Be}$ and γ rays

(b) bombardment of ${}^{9}\text{Be}$ with ${}^{2}_{1}\text{H}$ to produce ${}^{10}\text{B}$

(c) bombardment of ${}^{14}\text{N}$ with neutrons to produce ${}^{14}\text{C}$

12. Write equations for the following nuclear reactions.

(a) bombardment of ${}^{238}\text{U}$ with α particles to produce ${}^{239}\text{Pu}$

(b) bombardment of tritium (${}^{3}_{1}\text{H}$) with ${}^{2}_{1}\text{H}$ to produce ${}^{4}\text{He}$

(c) bombardment of ${}^{33}\text{S}$ with neutrons to produce ${}^{33}\text{P}$

13. Write nuclear equations to represent the formation of an isotope of element 111 with a mass number of 272 by the bombardment of bismuth-209 by nickel-64 nuclei, followed by a succession of five α-particle emissions.

14. Write nuclear equations to represent the formation of a hypothetical isotope of element 118 with a mass number of 293 by the bombardment of lead-208 by krypton-86 nuclei, followed by a chain of α-particle emissions to the element seaborgium.

15. Scientists from Dubna, Russia, observed the existence of elements 118 and 116 at the Joint Institute for Nuclear Research U400 cyclotron in 2005. This was the result of bombarding calcium-48 ions on a californium-249 target. Write a complete nuclear equation for this reaction.

16. The immediate decay product of element 118 is thought to be element 116. Write a complete nuclear equation for this reaction.

17. Element-120 is located in a region of the neutron versus proton map known as the island of stability. Write a nuclear equation for the generation of element-120 by bombarding iron isotopes on a plutonium target.

18. Another possible nuclear reaction leading to the formation of element-120 is between uranium-238 and nickel-64. Write a nuclear equation for this nuclear reaction.

Rate of Radioactive Decay

19. Of the radioactive nuclides in Table 25.1,

(a) which one has the largest value for the decay constant, λ?

(b) Which one loses 75% of its radioactivity in approximately one month?

(c) Which ones lose more than 99% of their radioactivity in one month?

20. In a comparison of two radioisotopes, isotope A requires 18.0 hours for its decay rate to fall to $\frac{1}{16}$ its initial value, while isotope B has a half-life that is 2.5 times that of A. How long does it take for the decay rate of isotope B to decrease to $\frac{1}{32}$ of its initial value?

21. The disintegration rate for a sample containing ${}^{60}_{27}\text{Co}$ as the only radioactive nuclide is 6740 dis h^{-1}. The half-life of ${}^{60}_{27}\text{Co}$ is 5.2 years. Estimate the number of atoms of ${}^{60}_{27}\text{Co}$ in the sample.

22. How many years must the radioactive sample of Exercise 21 be maintained before the disintegration rate falls to 101 dis min^{-1}?

23. A sample containing ${}^{224}_{88}\text{Ra}$, which decays by α-particle emission, disintegrates at the following rate, expressed as disintegrations per minute or counts per minute (cpm): $t = 0$, 1000 cpm; $t = 1$ h, 992 cpm; $t = 10$ h, 924 cpm; $t = 100$ h, 452 cpm;

$t = 250$ h, 138 cpm. What is the half-life of this nuclide?

24. Iodine-129 is a product of nuclear fission, whether from an atomic bomb or a nuclear power plant. It is a β^- emitter with a half-life of 1.7×10^7 years. How many disintegrations per second would occur in a sample containing 1.00 mg ${}^{129}\mathrm{I}$?

25. Suppose that a sample containing ${}^{32}\mathrm{P}$ has an activity 1000 times the detectable limit. How long would an experiment have to be run with this sample before the radioactivity could no longer be detected?

26. What mass of carbon-14 must be present in a sample to have an activity of 1.00 mCi?

Age Determinations with Radioisotopes

27. A wooden object is claimed to have been found in an Egyptian pyramid and is offered for sale to an art museum. Radiocarbon dating of the object reveals a disintegration rate of 10.0 dis min^{-1} g^{-1}. Do you think the object is authentic? Explain.

28. The lowest level of ${}^{14}\mathrm{C}$ activity that seems possible for experimental detection is 0.03 dis min^{-1} g^{-1}. What is the maximum age of an object that can be determined by the carbon-14 method?

29. What should be the mass ratio ${}^{208}\mathrm{Pb}/{}^{232}\mathrm{Th}$ in a meteorite that is approximately 2.7×10^9 years old? The half-life of ${}^{232}\mathrm{Th}$ is 1.39×10^{10} years. [*Hint:* One ${}^{208}\mathrm{Pb}$ atom is the final decay product of one ${}^{232}\mathrm{Th}$ atom.]

30. Concerning the decay of ${}^{232}\mathrm{Th}$ described in Exercise 29, a certain rock has a ${}^{208}\mathrm{Pb}/{}^{232}\mathrm{Th}$ mass ratio of 0.25/1.00. Estimate the age of the rock.

31. A lunar rock was analyzed for argon by mass spectrometry and for potassium by atomic absorption. The results of these analyses showed that the sample contained 3.02×10^{-5} mL g^{-1} of argon and 0.083% of potassium. The half-life of potassium-40 is 1.248×10^9 y. Calculate the age of the lunar rock.

32. What is the age of a piece of volcanic rock that has a mass ratio of argon-40 to potassium-40 of 2.9? The half-life of potassium-40 by β decay is 1.248×10^9 y and by electron capture $t_{1/2} = 1.4 \times 10^9$ y.

Energetics of Nuclear Reactions

33. Using appropriate equations in the text, determine **(a)** the energy in joules corresponding to the destruction of 6.02×10^{-23} g of matter; **(b)** the energy in megaelectronvolts that would be released if one α particle were completely destroyed.

34. The measured mass of the nucleus of an atom of silver-107 is 106.879289 u. For this atom, determine the binding energy per nucleon in megaelectronvolts.

35. Use the electron mass from Table 2.1 and the measured mass of the nuclide ${}^{19}_{9}\mathrm{F}$, 18.998403 u, to determine the binding energy per nucleon (in megaelectronvolts) of this atom.

36. Use the electron mass from Table 2.1 and the measured mass of the nuclide ${}^{56}_{26}\mathrm{Fe}$, 55.934939 u, to determine the binding energy per nucleon (in megaelectronvolts) of this atom.

37. Calculate the energy, in megaelectronvolts, released in the nuclear reaction

$$ {}^{10}_{5}\mathrm{B} + {}^{4}_{2}\mathrm{He} \longrightarrow {}^{13}_{6}\mathrm{C} + {}^{1}_{1}\mathrm{H} $$

The nuclidic masses are ${}^{10}_{5}\mathrm{B} = 10.01294$ u; ${}^{4}_{2}\mathrm{He} = 4.00260$ u; ${}^{13}_{6}\mathrm{C} = 13.00335$ u; ${}^{1}_{1}\mathrm{H} = 1.00783$ u.

38. You are given the following nuclidic masses: ${}^{6}_{3}\mathrm{Li} = 6.01513$ u; ${}^{4}_{2}\mathrm{He} = 4.00260$ u; ${}^{3}_{1}\mathrm{H} = 3.01604$ u; ${}^{1}_{0}\mathrm{n} = 1.008665$ u. How much energy, in megaelectronvolts, is released in the following nuclear reaction?

$$ {}^{6}_{3}\mathrm{Li} + {}^{1}_{0}\mathrm{n} \longrightarrow {}^{4}_{2}\mathrm{He} + {}^{3}_{1}\mathrm{H} $$

39. Calculate the number of neutrons that could be created with 6.75×10^6 MeV of energy.

40. When β^+ and β^- particles collide, they annihilate each other, producing two γ rays that move away from each other along a straight line. What is the approximate energies of these two γ rays, in MeV?

Nuclear Stability

41. Which member of the following pairs of nuclides would you expect to be most abundant in natural sources: **(a)** ${}^{20}_{10}\mathrm{Ne}$ or ${}^{22}_{10}\mathrm{Ne}$; **(b)** ${}^{17}_{8}\mathrm{O}$ or ${}^{18}_{8}\mathrm{O}$; **(c)** ${}^{6}_{3}\mathrm{Li}$ or ${}^{7}_{3}\mathrm{Li}$? Explain your reasoning.

42. Which member of the following pairs of nuclides would you expect to be most abundant in natural sources: **(a)** ${}^{40}_{20}\mathrm{Ca}$ or ${}^{42}_{20}\mathrm{Ca}$; **(b)** ${}^{31}_{15}\mathrm{P}$ or ${}^{32}_{15}\mathrm{P}$; **(c)** ${}^{63}_{30}\mathrm{Zn}$ or ${}^{64}_{30}\mathrm{Zn}$? Explain your reasoning.

43. One member each of the following pairs of radioisotopes decays by β^- emission, and the other by positron (β^+) emission: **(a)** ${}^{29}_{15}\mathrm{P}$ and ${}^{33}_{15}\mathrm{P}$; **(b)** ${}^{120}_{53}\mathrm{I}$ and ${}^{134}_{53}\mathrm{I}$. Which is which? Explain your reasoning.

44. Each of the following isotopes is radioactive: **(a)** ${}^{28}_{15}\mathrm{P}$; **(b)** ${}^{45}_{19}\mathrm{K}$; **(c)** ${}^{73}_{30}\mathrm{Zn}$. Which would you expect to decay by β^+ emission?

45. Some nuclides are said to be doubly magic. What do you suppose this term means? Postulate some nuclides that might be doubly magic, and locate them in Figure 25-7.

46. Both β^- and β^+ emissions are observed for artificially produced radioisotopes of low atomic numbers, but only β^- emission is observed with naturally occurring radioisotopes of high atomic number. Why do you suppose this is so?

Fission and Fusion

47. Refer to the Integrative Example. In contrast to the Chernobyl accident, the 1979 nuclear accident at Three Mile Island released only 170 curies of ^{131}I. How many milligrams of ^{131}I does this represent?

48. Explain why more energy is released in a fusion process than in a fission process.

Effect of Radiation on Matter

49. Explain why the rem is more satisfactory than the rad as a unit for measuring radiation dosage.

50. Discuss briefly the basic difficulties in establishing the physiological effects of low-level radiation.

51. ^{90}Sr is both a product of radioactive fallout and a radioactive waste in a nuclear reactor. This radioisotope is a β^- emitter with a half-life of 27.7 years. Suggest reasons why ^{90}Sr is such a potentially hazardous substance.

52. ^{222}Rn is an α-particle emitter with a half-life of 3.82 days. Is it hazardous to be near a flask containing this isotope? Under what conditions might ^{222}Rn be hazardous?

Applications of Radioisotopes

53. Describe how you might use radioactive materials to find a leak in the $H_2(g)$ supply line in an ammonia synthesis plant.

54. Explain why neutron activation analysis is so useful in identifying trace elements in a sample, in contrast to ordinary methods of quantitative analysis, such as precipitation or titration.

55. A small quantity of NaCl containing radioactive $^{24}_{11}$Na is added to an aqueous solution of $NaNO_3$. The solution is cooled, and $NaNO_3$ is crystallized from the solution. Would you expect the $NaNO_3(s)$ to be radioactive? Explain.

56. The following reactions are carried out with HCl(aq) containing some tritium ($^3_1$H) as a tracer. Would you expect any of the tritium radioactivity to appear in the $NH_3(g)$? In the H_2O? Explain.

$$NH_3(aq) + HCl(aq) \longrightarrow NH_4Cl(aq)$$

$$NH_4Cl(aq) + NaOH(aq) \longrightarrow NaCl(aq) + H_2O(l) + NH_3(g)$$

Integrative and Advanced Exercises

57. In some cases, the most abundant isotope of an element can be established by rounding off the atomic mass to the nearest whole number, as in ^{39}K, ^{85}Rb, and ^{88}Sr. But in other cases, the isotope corresponding to the rounded-off atomic mass does not even occur naturally, as in ^{64}Cu. Explain the basis of this observation.

58. The overall change in the radioactive decay of $^{238}_{92}$U to $^{206}_{82}$Pb is the emission of eight α particles. Show that if this loss of eight α particles were not also accompanied by six β^- emissions, the product nucleus would still be radioactive.

59. Use data from the text to determine how many metric tons $(1 \text{ metric ton} = 1000 \text{ kg})$ of bituminous coal (85% C) would have to be burned to release as much energy as is produced by the fission of 1.00 kg $^{235}_{92}$U.

60. One method of dating rocks is based on their ^{87}Sr/^{87}Rb ratio. ^{87}Rb is a β^- emitter with a half-life of 5×10^{11} years. A certain rock has a mass ratio ^{87}Sr/^{87}Rb of 0.004/1.00. What is the age of the rock?

61. How many millicuries of radioactivity are associated with a sample containing 5.10 mg ^{229}Th, which has a half-life of 7340 years?

62. What mass of ^{90}Sr, with a half-life of 27.7 years, is required to produce 1.00 millicurie of radioactivity?

63. Refer to the Integrative Example. Another radioisotope produced in the Chernobyl accident was ^{137}Cs. If a 1.00 mg sample of ^{137}Cs is equivalent to 89.8 millicuries, what must be the half-life (in years) of ^{137}Cs?

64. The percent natural abundance of ^{40}K is 0.0117%. The radioactive decay of ^{40}K atoms occurs 89% by β^- emission; the rest is by electron capture and β^+ emission. The half-life of ^{40}K is 1.25×10^9 years. Calculate the number of β^- particles produced per second by the ^{40}K present in a 1.00 g sample of the mineral *microcline*, $KAlSi_3O_8$.

65. The carbon-14 dating method is based on the assumption that the rate of production of ^{14}C by cosmic ray bombardment has remained constant for thousands of years and that the ratio of ^{14}C to ^{12}C has also remained constant. Can you think of any effects of human activities that could invalidate this assumption in the future?

66. Calculate the minimum kinetic energy (in megaelectronvolts) that α particles must possess to produce the nuclear reaction

$$^4_2\text{He} + {}^{14}_7\text{N} \longrightarrow {}^{17}_8\text{O} + {}^1_1\text{H}$$

The nuclidic masses are $^4_2\text{He} = 4.00260$ u; $^{14}_7\text{N} = 14.00307$ u; $^1_1\text{H} = 1.00783$ u; $^{17}_8\text{O} = 16.99913$ u.

67. Hydrogen gas is spiked with tritium to the extent of 5.00% by mass. What is the activity in curies of a 4.65 L sample of this gas at 25.0 °C and 1.05 atm pressure? [*Hint:* Use 3.02 u as the atomic mass of tritium and data from elsewhere in the text, as necessary.]

68. A certain shale deposit containing 0.006% U by mass is being considered for use as a potential fuel in a breeder reactor. Assuming a density of 2.5 g/cm^3, how much energy could be released from 1.00×10^3 cm^3 of this material? Assume a fission energy of 3.20×10^{-11} J per fission event (that is, per U atom).

69. An ester forms from a carboxylic acid and an alcohol.

$$RCO_2H + HOR' \longrightarrow RCO_2R' + H_2O$$

This reaction is superficially similar to the reaction of an acid with a base such as sodium hydroxide. The mechanism of the reaction can be followed by using the tracer ^{18}O. This isotope is not radioactive, but other physical measurements can be used to detect its presence. When the *esterification* reaction is carried out with the alcohol containing oxygen-18 atoms, no oxygen-18 beyond its naturally occurring abundance is found in the water produced. How does this result affect the perception that this reaction is like an acid–base reaction?

70. The conversion of CO_2 into carbohydrates by plants via photosynthesis can be represented by the reaction

$$6\,CO_2(g) + 6\,H_2O \xrightarrow{\text{light}} C_6H_{12}O_6 + 6\,O_2(g)$$

To study the mechanism of photosynthesis, algae were grown in water containing ^{18}O, that is, $H_2{}^{18}O$. The oxygen evolved contained oxygen-18 in the same ratio to the other oxygen isotopes as the water in which the reaction was carried out. In another experiment, algae were grown in water containing only ^{16}O, but with oxygen-18 present in the CO_2. The oxygen evolved in this experiment contained no oxygen-18. What conclusion can you draw about the mechanism of photosynthesis from these experiments?

71. Assume that when Earth formed, uranium-238 and uranium-235 were equally abundant. Their current percent natural abundances are 99.28% uranium-238 and 0.72% uranium-235. Given half-lives of 4.5×10^9 years for uranium-238 and 7.1×10^8 years for uranium-235, determine the age of Earth corresponding to this assumption.

Feature Problems

72. The *packing fraction* of a nuclide is related to the fraction of the total mass of a nuclide that is converted to nuclear binding energy. It is defined as the fraction $(M - A)/A$, where M is the actual nuclidic mass and A is the mass number. Use data from a handbook (such as the *Handbook of Chemistry and Physics*, published by the CRC Press) to determine the packing fractions of some representative nuclides. Plot a graph of packing fraction versus mass number, and compare it with Figure 25-6. Explain the relationship between the two.

73. For medical uses, radon-222 formed in the radioactive decay of radium-226 is allowed to collect over the radium metal. Then, the gas is withdrawn and sealed into a glass vial. Following this, the radium is allowed to disintegrate for another period, when a new sample of radon-222 can be withdrawn. The procedure can be continued indefinitely. The process is somewhat complicated by the fact that radon-222 itself undergoes radioactive decay to polonium-218, and so on. The half-lives of radium-226 and radon-222 are 1.60×10^3 years and 3.82 days, respectively.

(a) Beginning with pure radium-226, the number of radon-222 atoms present starts at zero, increases for a time, and then falls off again. Explain this behavior. That is, because the half-life of radon-222 is so much shorter than that of radium-226, why doesn't the radon-222 simply decay as fast as it is produced, without ever building up to a maximum concentration?

(b) Write an expression for the rate of change (dD/dt) in the number of atoms (D) of the radon-222 daughter in terms of the number of radium-226 atoms present initially (P_0) and the decay constants of the parent (λ_p) and daughter (λ_d).

(c) Integration of the expression obtained in part (b) yields the following expression for the number of atoms of the radon-222 daughter (D) present at a time t.

$$D = \frac{P_0\lambda_p(e^{-\lambda_p \times t} - e^{-\lambda_d \times t})}{\lambda_d - \lambda_p}$$

Starting with 1.00 g of pure radium-226, approximately how long will it take for the amount of radon-222 to reach its maximum value: one day, one week, one year, one century, or one millennium?

74. Radioactive decay and mass spectrometry are often used to date rocks after they have cooled from a magma. ^{87}Rb has a half-life of 4.8×10^{10} years and follows the radioactive decay

$$^{87}Rb \longrightarrow {}^{87}Sr + \beta^-$$

A rock was dated by assaying the product of this decay. The mass spectrum of a homogenized sample of rock showed the $^{87}Sr/^{86}Sr$ ratio to be 2.25. Assume that the original $^{87}Sr/^{86}Sr$ ratio was 0.700 when the rock cooled. Chemical analysis of the rock gave 15.5 ppm Sr and 265.4 ppm Rb, using the average atomic masses from a periodic table. The other isotope ratios were $^{86}Sr/^{88}Sr = 0.119$ and $^{84}Sr/^{88}Sr = 0.007$. The isotopic ratio for $^{87}Rb/^{85}Rb$ is 0.330. The isotopic masses are as follows:

Isotope	Atomic Mass, u
^{87}Rb	86.909
^{85}Rb	84.912
^{88}Sr	87.906
^{86}Sr	85.909
^{84}Sr	83.913
^{87}Sr	86.909

Calculate the following:

(a) the average atomic mass of Sr in the rock

(b) the original concentration of Rb in the rock in ppm

(c) the percentage of rubidium-87 decayed in the rock

(d) the time since the rock cooled

Self-Assessment Exercises

75. In your own words, define the following symbols: **(a)** α; **(b)** β^-; **(c)** β^+; **(d)** γ; **(e)** $t_{1/2}$.

76. Briefly describe each of the following ideas, phenomena, or methods: **(a)** radioactive decay series; **(b)** charged-particle accelerator; **(c)** neutron-to-proton ratio; **(d)** mass–energy relationship; **(e)** background radiation.

77. Explain the important distinctions between each pair of terms: **(a)** electron and positron; **(b)** half-life and decay constant; **(c)** mass defect and nuclear binding energy; **(d)** nuclear fission and nuclear fusion; **(e)** primary and secondary ionization.

78. Which of the following types of radiation is deflected in a magnetic field? **(a)** X ray; **(b)** γ ray; **(c)** β ray; **(d)** neutrons.

79. A process that produces a one-unit increase in atomic number is **(a)** electron capture; **(b)** β^- emission; **(c)** α emission; **(d)** γ-ray emission.

80. Of the following nuclides, the one most likely to be radioactive is **(a)** ^{31}P; **(b)** ^{66}Zn; **(c)** ^{35}Cl; **(d)** ^{108}Ag.

81. One of the following elements has eight naturally occurring *stable* isotopes. We should expect that one to be **(a)** Ra; **(b)** Au; **(c)** Cd; **(d)** Br.

82. Of the following nuclides, the highest nuclear binding energy per nucleon is found in **(a)** $^{3}_{1}H$; **(b)** $^{16}_{8}O$; **(c)** $^{56}_{26}Fe$; **(d)** $^{235}_{92}U$.

83. The most radioactive of the isotopes of an element is the one with the largest value of its **(a)** half-life, $t_{1/2}$; **(b)** neutron number, N; **(c)** mass number, Z; **(d)** radioactive decay constant, λ.

84. Given a radioactive nuclide with $t_{1/2} = 1.00$ h and a current disintegration rate of 1000 atoms s^{-1}, three hours from now the disintegration rate will be **(a)** 1000 atoms s^{-1}; **(b)** 333 atoms s^{-1}; **(c)** 250 atoms s^{-1}; **(d)** 125 atoms s^{-1}.

85. Write nuclear equations to represent
(a) the decay of ^{214}Ra by α-particle emission
(b) the decay of ^{205}At by positron emission
(c) the decay of ^{212}Fr by electron capture
(d) the reaction of two deuterium nuclei (deuterons) to produce a nucleus of $^{3}_{2}He$
(e) the production of $^{243}_{97}Bk$ by the α-particle bombardment of $^{241}_{95}Am$
(f) a nuclear reaction in which thorium-232 is bombarded with α particles, producing a new nuclide and four neutrons.

86. ^{232}Ra has a half-life of 11.4 d. How long would it take for the radioactivity associated with a sample of ^{232}Ra to decrease to 1% of its current value?

87. A sample of radioactive $^{35}_{16}S$ disintegrates at a rate of 1.00×10^3 atoms min^{-1}. The half-life of $^{35}_{16}S$ is 87.9 d. How long will it take for the activity of this sample to decrease to the point of producing **(a)** 253; **(b)** 104; and **(c)** 52 dis min^{-1}?

88. Neutron bombardment of ^{23}Na produces an isotope that is a β emitter. After β emission, the final product is **(a)** ^{24}Na; **(b)** ^{23}Mg; **(c)** ^{23}Ar; **(d)** ^{24}Ar; **(e)** none of these.

89. A nuclide has a decay rate of $2.00 \times 10^{10}\ s^{-1}$. After 25.0 days, its decay rate is $6.25 \times 10^{8}\ s^{-1}$. What is the nuclide's half-life? **(a)** 25.0 d; **(b)** 12.5 d; **(c)** 50.0 d; **(d)** 5.00 d; **(e)** none of these.

90. A nuclide has a half-life of 1.91 y. Its decay constant has a numerical value of **(a)** 1.32; **(b)** 2.76; **(c)** 0.363; **(d)** 0.524; **(e)** none of these.

91. A nuclide has a decay constant of $4.28 \times 10^{-4}\ h^{-1}$. If the activity of a sample is $3.14 \times 10^{5}\ s^{-1}$, how many atoms of the nuclide are present in the sample? **(a)** 2.64×10^{12}; **(b)** 7.34×10^{8}; **(c)** 2.04×10^{5}; **(d)** 4.40×10^{10}; **(e)** none of these.

92. Based on magic numbers, which nuclide is the least stable? **(a)** ^{59}Ni; **(b)** ^{51}V; **(c)** ^{122}Sb; **(d)** ^{16}O; **(e)** ^{12}C.

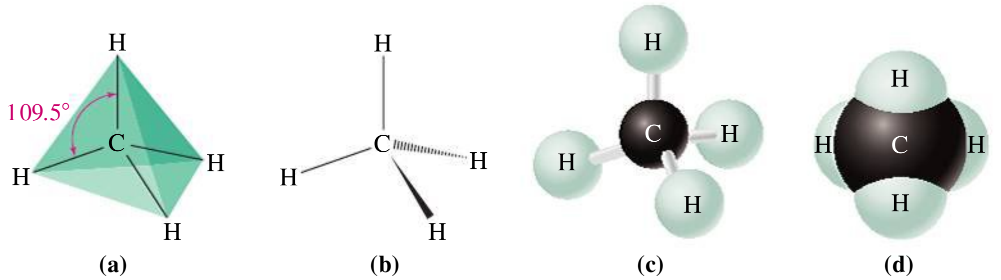
26-8 From Molecular Formula to Molecular Structure

To early nineteenth-century chemists, organic chemistry meant the study of compounds obtainable only from living matter, which was thought to have the "vital force" needed to make these compounds. In 1828, Friedrich Wöhler set out to synthesize ammonium cyanate, NH_4OCN, using the reaction below:

$$AgOCN(s) + NH_4Cl(aq) \xrightarrow{\Delta} AgCl(s) + NH_4OCN(aq)$$

The white crystalline solid he obtained from the solution had none of the properties of ammonium cyanate, even though it had the same composition. The compound was not NH_4OCN but $(NH_2)_2CO$—*urea*, an organic compound. As Wöhler excitedly reported to J. J. Berzelius, "I must tell you that I can make urea without the use of kidneys, either man or dog. Ammonium cyanate is urea."

Since that time, chemists have synthesized millions of organic compounds, and today organic compounds represent about 98% of all known chemical substances. In this chapter, we build on the introduction to organic compounds in Chapter 3 by exploring some of the principal types



▲ FIGURE 26-1
Representation of the methane molecule
(a) Tetrahedral structure showing bond angle. **(b)** Dashed-wedged line structure convention used to suggest a three-dimensional structure through a structural formula. The solid lines represent bonds in the plane of the page. The dashed wedge projects *away* from the viewer (behind the plane of the page), and the heavy wedge projects *toward* the viewer (out of the page). **(c)** Ball-and-stick model. **(d)** Space-filling model.

of organic compounds. In this chapter, we will focus on the structures and properties of organic compounds, and we will consider the preparation and some uses of these compounds. In the next chapter, we will turn our attention to reactions that interconvert these compounds.

KEEP IN MIND

that the hybridization of the C atoms in ethane and propane is sp^3, as in methane. The tetrahedral geometry at the C atoms in alkanes means that the propane chain is not linear.

26-1 Organic Compounds and Structures: An Overview

As we learned in Chapter 3, organic compounds contain carbon and hydrogen atoms or carbon and hydrogen in combination with a few other types of atoms, such as oxygen, nitrogen, and sulfur. Carbon is singled out for special study because the ability of C atoms to form strong covalent bonds with one another allows them to join together into straight chains, branched chains, and rings. The nearly infinite number of possible bonding arrangements of C atoms accounts for the vast number and variety of organic compounds.

The simplest organic compounds are those of carbon and hydrogen—**hydrocarbons**—and the simplest hydrocarbon is methane, CH_4, the chief constituent of natural gas.

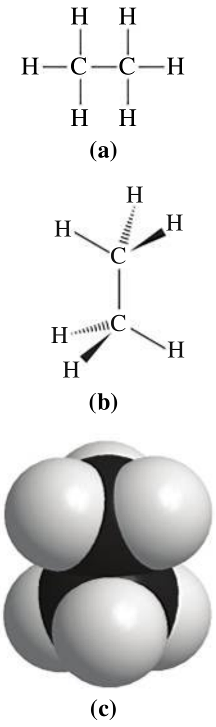
From VSEPR theory we expect the electron group geometry around the central C atom in CH_4 to be tetrahedral, as illustrated in Figure 26-1(a). The four H atoms are equivalent: They are equidistant from the C atom and attached to it by covalent bonds of equal strength. The angle between any two $C{-}H$ bonds is 109.5°. In Figure 26-1(b), the three-dimensional structure of CH_4 is represented by using the **dashed and solid wedge line notation** we introduced in Chapter 10. Other commonly employed depictions of methane are also shown in Figure 26-1.

The bonding in CH_4 is most easily described in terms of valence bond theory. As shown in Figure 11-7 (page 454), each of the carbon–hydrogen bonds is a σ bond formed by the overlap of a 1*s* orbital on hydrogen with an sp^3 orbital on carbon.

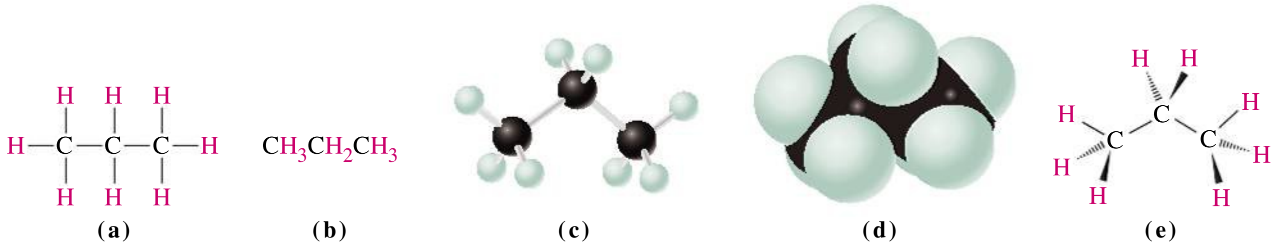
The removal of one H atom from a CH_4 molecule leaves the $-CH_3$ group. Now imagine forming a covalent bond between two $-CH_3$ groups. The resulting molecule is *ethane*, C_2H_6 (Fig. 26-2). By increasing the number of C atoms in the chain, we can obtain still more hydrocarbons. The three-carbon molecule propane, C_3H_8, is pictured in Figure 26-3.

Constitutional Isomerism in Organic Compounds

As we have previously learned, compounds that have the same molecular formula but different structural formulas are called *isomers*. Forms of isomerism



▲ FIGURE 26-2
The ethane molecule, C_2H_6
(a) Structural formula. **(b)** Dashed-wedged line structure. **(c)** Space-filling model.



▲ FIGURE 26-3

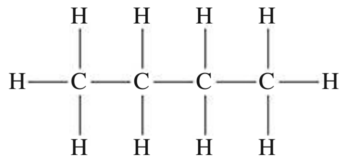
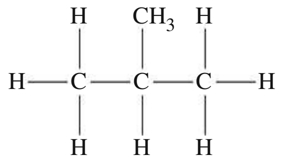
abound in organic chemistry. We will encounter two types of isomers in this chapter—constitutional isomers and stereoisomers—but our focus in this section is on constitutional isomers. **Constitutional isomers** have different bond connectivities and thus different skeletal structures. For example, C_4H_{10} has two constitutional isomers, as shown below:

◀ Because constitutional isomers have different structural formulas, they are sometimes called structural isomers. However, the term is not recommended by IUPAC.



Butane



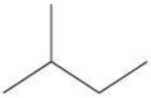
Methylpropane

Butane has a single chain of four carbon atoms. Methylpropane has a three-carbon chain with a $-CH_3$ group bonded to the second carbon. Butane is called a straight-chain hydrocarbon—although the molecule does not have a straight shape—and methylpropane is an example of a branched-chain hydrocarbon. Because butane and methylpropane have different structural formulas, they are different compounds and have different physical properties. For example, the boiling point of butane is −0.5 °C and that of methylpropane is −11.7 °C.

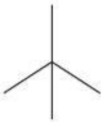
The number of constitutional isomers increases rapidly with the number of carbon atoms. For example, C_5H_{12} has only three isomers (see Example 26-1) whereas $C_{10}H_{22}$ has 75 and $C_{20}H_{42}$ has more than 300,000!

In Chapter 3, we mentioned a way of greatly simplifying the writing of organic structures. We draw lines to represent chemical bonds, and wherever a line ends or meets another line, there is a C atom. We then assume that enough H atoms are bonded to the C atoms to satisfy the need for each C atom to form *four* bonds. Such structural formulas are called *line-angle formulas*, or *line structures*. Notice that in the line-angle formulas written below for the three isomers in Example 26-1, we arrange the lines in a zigzag fashion, which is consistent with the three-dimensional structures of these molecules.

(1)



(2)



(3)

Nomenclature

Early organic chemists often assigned names related to the origin or properties of new compounds. Some of these names are still in common use. Citric acid is found in citrus fruit; uric acid is present in urine; formic acid is found in ants (from the Latin word for ant, *formica*); and morphine induces sleep (from *Morpheus*, the ancient Greek god of sleep). As thousands upon thousands of new compounds were synthesized, it became apparent that a system of common names was unworkable. Following several interim systems, one recommended by the International Union of Pure and Applied Chemistry (IUPAC) was adopted.

26-1 CONCEPT ASSESSMENT

In 1874, van't Hoff and Le Bel published separate papers advancing the hypothesis that the four bonds from a central carbon extend tetrahedrally. This marked the beginning of the field of stereochemistry. Part of their justification was that there was only one known compound with the formula CH_2X_2. Using the compound CH_2F_2 as an example, determine the expected number of isomers if the orientation of the bonds to a carbon atom is tetrahedral and the expected number if the orientation is square-planar.

EXAMPLE 26-1 Identifying Isomers

Write structural formulas for all the constitutional isomers with the molecular formula C_5H_{12}.

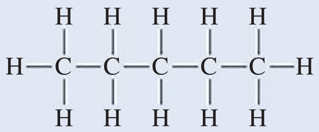
Analyze

First we write the longest chain of C atoms and add an appropriate number of H atoms (12, in this case) to give each C atom four bonds. Next, we look for isomers that have fewer carbon atoms in the longest chain.

Solve

The longest chain of carbon atoms that we can draw has five carbon atoms in it. When we add hydrogen atoms to give each carbon atom four bonds, we obtain structure (1).

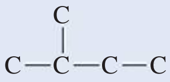
(1)



$$\begin{array}{ccccccccccccc} & & H & & H & & H & & H & & H & & \\ & & \mid & & \mid & & \mid & & \mid & & \mid & & \\ H & - & C & - & C & - & C & - & C & - & C & - & H \\ & & \mid & & \mid & & \mid & & \mid & & \mid & & \\ & & H & & H & & H & & H & & H & & \end{array}$$

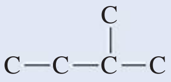
Now, let's look for isomers with four C atoms in the longest chain and one C atom as a branch (five C atoms in all). There is only *one* possibility. Notice that if structure (2) is flipped from left to right, the identical structure (2′) is obtained.

(2)



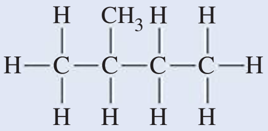
$$\begin{array}{ccccccc} & & C & & & & \\ & & \mid & & & & \\ C & - & C & - & C & - & C \end{array}$$

(2′)



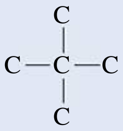
$$\begin{array}{ccccccc} & & & & C & & \\ & & & & \mid & & \\ C & - & C & - & C & - & C \end{array}$$

Again, we complete the structure of this isomer by adding H atoms.



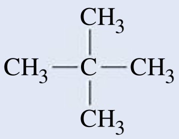
$$\begin{array}{ccccccccccc} & & H & & CH_3 & & H & & H & & \\ & & \mid & & \mid & & \mid & & \mid & & \\ H & - & C & - & C & - & C & - & C & - & H \\ & & \mid & & \mid & & \mid & & \mid & & \\ & & H & & H & & H & & H & & \end{array}$$

Finally, let's consider a three-carbon chain with two one-carbon branches. Again, there is only *one* possibility.



$$\begin{array}{ccccc} & & C & & \\ & & \mid & & \\ C & - & C & - & C \\ & & \mid & & \\ & & C & & \end{array}$$

that is,



$$\begin{array}{ccccc} & & CH_3 & & \\ & & \mid & & \\ CH_3 & - & C & - & CH_3 \\ & & \mid & & \\ & & CH_3 & & \end{array}$$

The number of isomers with the formula C_5H_{12} is three.

Assess

We must be careful to recognize when two possible structures are actually the same structure, as was the case for structures (2) and (2′).

PRACTICE EXAMPLE A: Write condensed structural formulas for the five constitutional isomers with the formula C_6H_{14}.

PRACTICE EXAMPLE B: Write condensed structural formulas for the nine constitutional isomers with the formula C_7H_{16}.

NOMENCLATURE
CHIMIQUE
1892-1992
90
HELVETIA

▲ A Swiss stamp commemorating the 100th anniversary of an international congress in Geneva, at which a systematic nomenclature of organic compounds was adopted.

In this introduction to nomenclature, we will consider only hydrocarbons with all carbon-to-carbon bonds as single bonds. These are known as **saturated hydrocarbons**, or alkanes. We have no trouble naming the first few: CH_4, methane; C_2H_6, ethane; C_3H_8, propane. We encounter our first difficulty with C_4H_{10}, which has two constitutional isomers. This problem is resolved by assigning the name *butane* to the straight-chain isomer, $CH_3CH_2CH_2CH_3$, and *isobutane* to the branched-chain isomer, $CH_3CH(CH_3)_2$. This method is inadequate for the C_5H_{12} alkanes, for which there are three structural isomers (Example 26-1), and it is even less satisfactory for alkanes with greater numbers of C atoms.

To be able to name molecules that have even greater complexity, we must first consider the nature of some of the possible side chains. A side chain is an alkane with one hydrogen atom removed. The resulting group of atoms is called an **alkyl** group, which is named by replacing the ending *-ane* in the corresponding alkane with *-yl*. For example, $—CH_3$ is the methyl group and $—CH_2CH_2CH_3$ is the propyl group. An alkyl side chain is also called a substituent alkyl group because it replaces (substitutes for) a hydrogen atom in the main chain. Table 26.1 shows some common alkyl groups. We see that some of the names incorporate prefixes, such as *sec-*, an abbreviation for secondary, or *tert-*, an abbreviation for tertiary. We use the terms *primary, secondary*, and *tertiary* to provide information about the nature of carbon atoms in organic molecules. A **primary carbon** is attached to one other carbon atom. Carbon atoms at the ends of an alkane chain are always primary carbons. The hydrogen atoms attached to a primary carbon atom are called **primary hydrogen atoms**, and an alkyl group formed by removing a primary hydrogen atom is a primary group. A **secondary carbon** is attached to two other carbon atoms, and a **tertiary carbon**, to three others. Their hydrogen atoms are labeled similarly. As we can see from Table 26.1, the removal of a secondary hydrogen results in the formation of a secondary alkyl group, and the removal of a tertiary hydrogen results in a tertiary alkyl group. Finally, a carbon attached to four carbon atoms is called **quaternary**. The classification of carbon and hydrogen atoms is illustrated in Figure 26-4.

◀ When distinguishing the different types of H and C atoms, the symbols 1°, 2°, 3°, and 4° are often used in place of the words primary, secondary, tertiary, and quaternary.

The following rules enable us to name branched-chain hydrocarbons unambiguously as long as we apply the rules in sequence.

1. Select the *longest* continuous carbon chain in the molecule and use the hydrocarbon name of this chain as the base name. Except for the common names methane, ethane, propane, and butane, standard Greek prefixes relate the name to the number of C atoms in the chain, as in *pent*ane (C_5), *hex*ane (C_6), *hep*tane (C_7), *oct*ane (C_8), ...
2. Consider every branch of the main branch to be a substituent alkyl group. Table 26.1 gives the names of common alkyl substituents. When the substituent is more complex, we use the rules given previously to name the side group, bearing in mind that we would change the *-ane* ending to *-yl*.
3. Number the C atoms of the continuous base chain so that the substituents appear *at the lowest numbers* possible.
4. Name each substituent according to its chemical identity and the number of the C atom to which it is attached. For identical substituents use *di, tri, tetra*, and so on, and write the appropriate carbon number for each substituent.
5. Separate numbers from one another with commas but no spaces, and separate numbers from letters with hyphens.
6. List the substituents *alphabetically* by name. When determining alphabetical order, the prefixes *di-*, *tri-*, *sec-*, and *tert-* are ignored. Thus, *tert*-butyl, precedes methyl in the name 4-*tert*-butyl-2-methylheptane. However, the prefix *iso-* is not ignored when deciding the alphabetical order.

◀ Do not try to memorize these rules at the outset. Refer to them as you proceed through the examples, and they will become part of your vocabulary of organic chemistry.

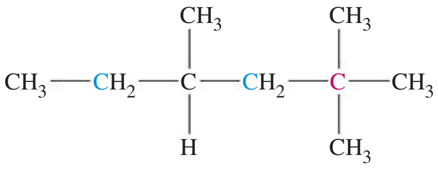
26-2 CONCEPT ASSESSMENT

Is it possible that an organic molecule contains a quaternary hydrogen atom?

TABLE 26.1 Some Common Alkyl Groups

Common Name	IUPAC Name	Structural Formula
Methyl	Methyl	$-CH_3$
Ethyl	Ethyl	$-CH_2CH_3$
Propyl[a]	Propyl	$-CH_2CH_2CH_3$
Isopropyl	1-Methylethyl	 $CH_3\underset{\vert}{C}HCH_3$
Butyl[a]	Butyl	$-CH_2CH_2CH_2CH_3$
Isobutyl	2-Methylpropyl	 $-CH_2\overset{CH_3}{\overset{\vert}{C}}HCH_3$
sec-Butyl[b]	1-Methylpropyl	 $CH_3\underset{\vert}{C}HCH_2CH_3$
tert-Butyl[c]	1,1-Dimethylethyl	 $CH_3\underset{\vert}{\overset{CH_3}{\overset{\vert}{C}}}CH_3$

[a] In the past, the prefix *normal* or *n*- was used for a straight-chain alkyl group, such as *n*-propyl or *n*-butyl.
[b] *sec* = secondary
[c] *tert* = tertiary



2,2,4-trimethylhexane

C = primary carbon
C = secondary carbon
C = tertiary carbon
C = quaternary carbon

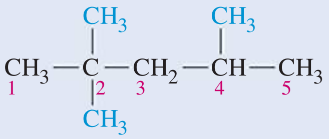
▲ FIGURE 26-4
Classification of carbon and hydrogen atoms
In 2,2,4-trimethylhexane, there are five primary carbons (shown in black), two secondary carbon atoms (shown in blue), one tertiary carbon atom (shown in gray), and one quaternary carbon atom (shown in red). The hydrogen atoms bonded to a primary carbon atom are called primary hydrogen atoms. Similarly, secondary or tertiary hydrogens are bonded, respectively, to secondary or tertiary carbon atoms.

Functional Groups

Organic compounds typically contain elements in addition to carbon and hydrogen. These elements occur as distinctive groupings of one or several atoms called **functional groups**. We have already encountered (in Chapter 3) a

EXAMPLE 26-2 Naming an Alkane Hydrocarbon

Give an appropriate IUPAC name for the following compound, an important constituent of gasoline.



Analyze

We apply the rules listed above. With practice, you will be able to apply the rules without referring back to the list.

Solve

The C atoms are numbered in red, and the side-chain substituents to be named are shown in blue. The longest chain of C atoms is five, and the carbons are numbered so that the one with two substituent groups is number 2 instead of number 4. Each substituent is a methyl group, $-CH_3$. Two methyl groups are on the second C atom, and one methyl group is on the fourth C atom. The correct name is 2,2,4-trimethylpentane.

Assess

If we had numbered the C atoms from right to left, we would have obtained the name 2,4,4-trimethylpentane. This is *not* an acceptable name because it does not use the *smallest* numbers possible.

PRACTICE EXAMPLE A: Give an IUPAC name for $CH_3CH_2CH(CH_3)CH_2CH_2C(CH_3)_2CH_2CH_3$. (*Hint:* Any CH_3 group enclosed in parentheses is bonded only to the C atom preceding it.)

PRACTICE EXAMPLE B: Give an IUPAC name for $CH_3CH_2CH(CH_3)CH_2CH_2CH(CH_3)CH_2CH_3$. (*Hint:* See the hint given in Practice Example A.)

EXAMPLE 26-3 Writing the Formula to Correspond to the Name of an Alkane Hydrocarbon

Write a condensed structural formula for 4-*tert*-butyl-2-methylheptane.

Analyze

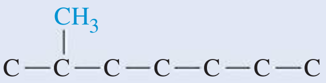
The name tells us that the compound is a heptane with two substituent groups, *tert*-butyl and methyl, positioned at carbons 4 and 2, respectively.

Solve

Because the compound is a heptane, the longest chain of C atoms is seven.

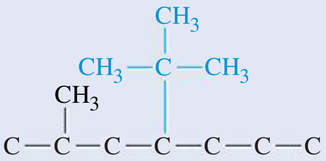
$C-C-C-C-C-C-C$

Starting on the left, we attach a methyl group to the second C atom.



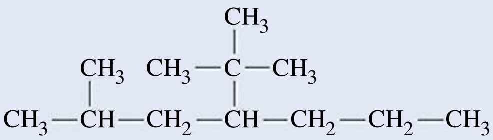
$$C-\overset{CH_3}{\overset{|}{C}}-C-C-C-C-C$$

Next, we attach a *tert*-butyl group to the fourth C atom.



$$C-\overset{CH_3}{\overset{|}{C}}-C-\overset{CH_3-\overset{CH_3}{\overset{|}{C}}-CH_3}{\overset{|}{C}}-C-C-C$$

Finally, we add the remaining hydrogen atoms to give each C atom four bonds.



$$CH_3-\overset{CH_3}{\overset{|}{CH}}-CH_2-\overset{CH_3-\overset{CH_3}{\overset{|}{C}}-CH_3}{\overset{|}{CH}}-CH_2-CH_2-CH_3$$

Assess

To check the answer, we use the nomenclature rules given on page 1152 to name the structure we've drawn. We should obtain the name that was given.

PRACTICE EXAMPLE A: Write a condensed structural formula for 3-ethyl-2,6-dimethylheptane.

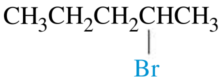
PRACTICE EXAMPLE B: Write a condensed structural formula for 3-isopropyl-2-methylpentane.

few functional groups, such as the —OH group in alcohols and the —COOH group in carboxylic acids. Table 26.2 lists the major types of organic compounds with their distinctive functional groups shown in red. The physical and chemical properties of organic molecules generally depend on the particular functional groups present. Compounds with the same functional group generally have similar chemical properties. Thus, a convenient way to study organic chemistry is to consider the properties associated with specific functional groups.

In some cases, a functional group simply takes the place of an H atom in a hydrocarbon chain or ring. Such is the case with alcohols and alkyl halides (also called haloalkanes). When naming alcohols and alkyl halides, we must identify the position of the —OH group or halogen atom in the molecule. For example, consider the following possibilities that arise when a Br atom takes the place of a hydrogen atom in pentane:

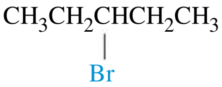
$CH_3CH_2CH_2CH_2CH_2Br$

1-Bromopentane



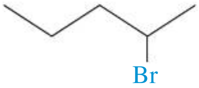
$$CH_3CH_2CH_2\underset{\underset{Br}{|}}{CH}CH_3$$

2-Bromopentane



$$CH_3CH_2\underset{\underset{Br}{|}}{CH}CH_2CH_3$$

3-Bromopentane



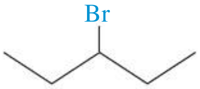


TABLE 26.2 Some Classes of Organic Compounds and Their Functional Groups

Class	General Structural Formula[a]	Example	Name of Example
Alkane	$R-H$	$CH_3CH_2CH_2CH_2CH_2CH_3$	Hexane
Alkene		$CH_2=CHCH_2CH_2CH_3$	1-Pentene
Alkyne	$-C\equiv C-$	$CH_3C\equiv CCH_2CH_2CH_2CH_2CH_3$	2-Octyne
Alcohol	$R-OH$	$CH_3CH_2CH_2CH_2OH$	1-Butanol
Alkyl halide	$R-X^b$	$CH_3CH_2CH_2CH_2CH_2CH_2Br$	1-Bromohexane
Ether	$R-O-R'$	$CH_3-O-CH_2CH_2CH_3$	1-Methoxypropane (methyl propyl ether)[c]
Amine	$R-NH_2$	$CH_3CH_2CH_2-NH_2$	1-Aminopropane (propylamine)[c]
Aldehyde	 $R-\overset{O}{\overset{\Vert}{C}}-H$	 $CH_3CH_2CH_2\overset{O}{\overset{\Vert}{C}}-H$	Butanal (butyraldehyde)[c]
Ketone	 $R-\overset{O}{\overset{\Vert}{C}}-R'$	 $CH_3CH_2\overset{O}{\overset{\Vert}{C}}CH_2CH_2CH_3$	3-Hexanone (ethyl propyl ketone)[c]
Carboxylic acid	 $R-\overset{O}{\overset{\Vert}{C}}-OH$	 $CH_3CH_2CH_2\overset{O}{\overset{\Vert}{C}}-OH$	Butanoic acid (butyric acid)[c]
Ester	 $R-\overset{O}{\overset{\Vert}{C}}-OR'$	 $CH_3CH_2CH_2\overset{O}{\overset{\Vert}{C}}-OCH_3$	Methyl butanoate (methyl butyrate)[c]
Amide	 $R-\overset{O}{\overset{\Vert}{C}}-NH_2$	 $CH_3CH_2CH_2\overset{O}{\overset{\Vert}{C}}-NH_2$	Butanamide (butyramide)[c]
Arene	$Ar-H^d$		Ethylbenzene
Aryl halide	$Ar-X^b$		Bromobenzene
Phenol	$Ar-OH$		4-Chlorophenol (p-chlorophenol)[c]

[a] The functional group is shown in red. R and R′ represent alkyl groups.
[b] X stands for a halogen atom: F, Cl, Br, or I.
[c] Common name.
[d] Ar stands for an aromatic (*aryl*) group such as the benzene ring.

These three monobromopentanes possess the same carbon skeleton and differ only in the position of the bromine atom on the carbon chain. Notice that we include the appropriate carbon number for the Br substituent when naming the compound.

We will discuss several classes of organic compounds in this chapter, focusing primarily on their structures and properties. In the next chapter, we will focus on some of their characteristic reactions.

26-3 CONCEPT ASSESSMENT

What is the IUPAC name for $CH_3CH_2CH_2CH(OH)CH_3$? You may find it useful to review Section 3-7.

26-2 Alkanes

In this section we will explore some properties of the alkanes. The essential characteristic of **alkane** hydrocarbon molecules is that they have only single covalent bonds. The bonds in these compounds are said to be *saturated*.

The alkanes range in complexity from methane, CH_4, to molecules containing fifty C atoms or more. Most have the formula C_nH_{2n+2}, and each alkane differs from the preceding one in a sequence by a $—CH_2—$, or *methylene* group. Substances whose molecules differ only by a constant unit such as $—CH_2—$ are said to form a **homologous series**. Members of such a series usually have closely related chemical and physical properties. The data in Table 26.3 indicate that boiling points of alkanes are related to polarizabilities and shapes in the ways discussed in Section 12-1. Intermolecular attractions between the straight-chain molecules are strongest, and these molecules have the highest boiling points. Isomers with more compact structures have lower boiling points.

◀ Alkanes are nonpolar, water-insoluble compounds with relatively low melting points and boiling points.

26-4 CONCEPT ASSESSMENT

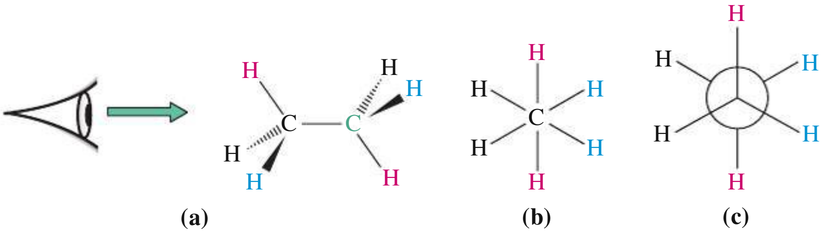
Illustrate the meaning of homologous series by writing a homologous series for alkyl halides.

Conformations

With ball-and-stick models, we can visualize an important type of motion in alkane molecules—rotation of groups with respect to one another about the σ bond connecting them. **Conformations** are different spatial arrangements that are possible in a molecule. One conformation can be converted into another by rotations about σ bonds. In Figure 26-5, we focus on one of the many possible conformations of the CH_3CH_3 molecule. The spatial arrangement of the H atoms can be seen more clearly if we view the molecule along the $C—C$ axis, as suggested in Figure 26-5(a). When the molecule is viewed in this way, the carbon atom toward the rear is obscured by the one in front, as shown in Figure 26-5(b), but the bonds to the hydrogen atoms are clearly seen. The view along the $C—C$ bond is shown in a slightly different way in Figure 26-5(c). In this

TABLE 26.3 Boiling Points of Some Isomeric Alkanes

Formula	Isomer	Boiling Point, °C	Formula	Isomer	Boiling Point, °C
C_4H_{10}	Butane	−0.5	C_6H_{14}	Hexane	68.7
	Methylpropane	−11.7		3-Methylpentane	63.3
C_5H_{12}	Pentane	36.1		2-Methylpentane	60.3
	2-Methylbutane	27.9		2,3-Dimethylbutane	58.0
	2,2-Dimethylpropane	9.5		2,2-Dimethylbutane	49.7



▲ FIGURE 26-5
Staggered conformation of ethane
When the ethane molecule is viewed along the C—C axis, as suggested in **(a)**, the rear carbon atom is obscured by the carbon atom in front, as shown in **(b)**. In the Newman projection, shown in **(c)**, the front carbon is located at the intersection of the three arms of the inverted Y and the rear carbon is represented by a circle.

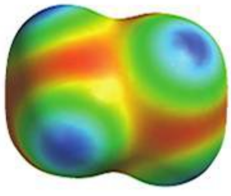
representation, called a *Newman projection,* the carbon atom toward the front is located at the point where the lines representing the three carbon–hydrogen bonds intersect with each other. The carbon atom toward the rear is depicted by a circle and its bonds project from the outer edge of the circle. Newman projections are used to represent the many different spatial arrangements of atoms that result from rotations about a σ bond. The arrangement (or conformation) shown in Figure 26-5 is called the *staggered conformation*. In this conformation, the carbon–hydrogen bonds in one $-\text{CH}_3$ group are positioned exactly halfway between those of the other $-\text{CH}_3$ group and the H atoms are located a maximum distance apart.

A second conformation can be obtained by rotating one of the methyl groups in the staggered conformation by 60° about the C—C axis, as suggested in Figure 26-6. When the resulting conformation is viewed along the C—C axis, all the hydrogen atoms on the first carbon atom are directly in front of those on the second carbon atom. This is called the *eclipsed* conformation. To make the three rear hydrogen atoms more visible in the Newman projection, they are drawn slightly out of the perfectly eclipsed position. The eclipsed and staggered conformations represent two extremes and all the possible conformations in between are called collectively *skew conformations*.

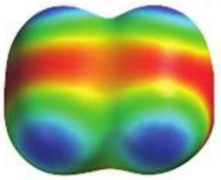
Electrostatic potential maps for the staggered and eclipsed conformations of ethane are shown in the margin. In the staggered conformation, the hydrogen atoms (in the blue regions) are as far apart from one another as possible, and in the eclipsed conformation, they are as close as possible.

Energy is required to convert from the staggered conformation to the eclipsed conformation, and for ethane, the energy required is about 12.0 kJ mol^{-1}. Because of this energy requirement, there is a *barrier to internal rotation*, and thus the $-\text{CH}_3$ groups in ethane do not rotate entirely freely about the C—C bond. However, the barrier to internal rotation is small enough that, at room

▶ Newman projections are named after an organic chemistry professor, Melvin S. Newman, from Ohio State University. He introduced these representations in 1952 to help students understand conformations, stereochemistry, and symmetry of organic molecules.



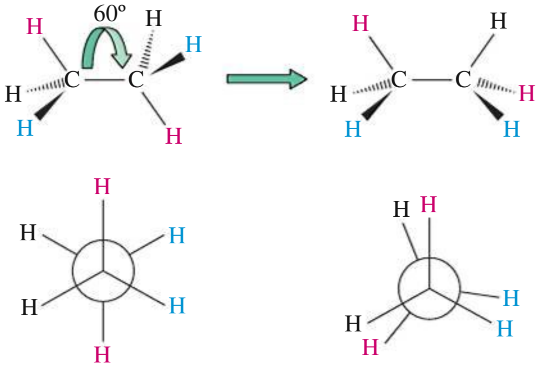
Staggered conformation



Eclipsed conformation

KEEP IN MIND

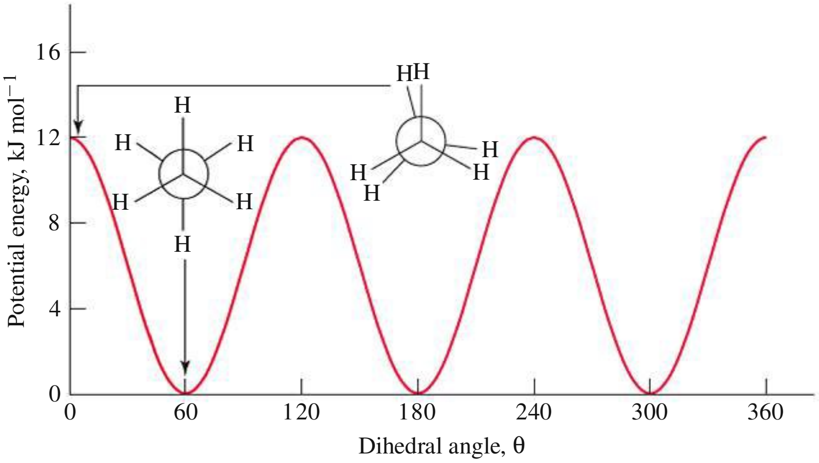
that the barrier to rotation in ethane (12 kJ mol^{-1}) is comparable to the strengths of various intermolecular forces we discussed in Chapter 12.



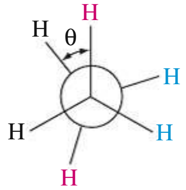
Staggered

Eclipsed

▶FIGURE 26-6
Staggered and eclipsed conformations of ethane
When the methyl group on the right is rotated by 60° about the C—C bond, the staggered conformation of ethane is converted into the eclipsed conformation.



▲ FIGURE 26-7
Potential energy diagram for the internal rotation of the methyl groups in ethane

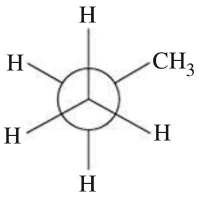


The dihedral angle, θ, refers to the angle of rotation about a carbon–carbon bond.

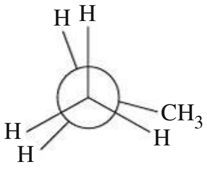
temperature, molecules interconvert rapidly from one conformation to another. For this reason, rotation about the C—C bond is sometimes called *free rotation*. The barrier to internal rotation arises because as the molecule converts from the staggered conformation through all the skew conformations to the eclipsed conformation, the C—H bonds of one —CH_3 group draw closer to the C—H bonds of the other —CH_3 group and the electrons in these bonds experience increased repulsion. The eclipsed conformation is highest in energy because in this conformation, the electrons in the C—H bonds of one methyl group are close to the electrons in the C—H bonds of the other methyl group.

The conversion from one conformation to another can be followed by using the dihedral angle, θ, which refers to the angle of rotation about the carbon–carbon bond, as shown in the margin. When $\theta = 0°$, the molecule is in the eclipsed conformation, and when $\theta = 60°$, it is in the staggered conformation. The energy changes that occur as the ethane molecule converts from one conformation to another are shown graphically in Figure 26-7. The difference in energy between the eclipsed and staggered conformations is called the rotational or **torsional energy**. In the eclipsed conformation, there are three C—H bond interactions, and thus each C—H bond interaction contributes 4.0 kJ mol^{-1}.

Let's consider rotation about a C—C bond in propane, $CH_3CH_2CH_3$, which is the next member of the homologous series. The potential energy diagram of propane is similar to that of ethane. However, an important difference is that the energy difference between the eclipsed and staggered conformations, and thus the barrier to rotation about a C—C bond, is slightly greater in propane (13.6 kJ mol^{-1}) than it is in ethane (12.0 kJ mol^{-1}). Newman projections for the conformations of propane can help us understand this difference. The Newman projections for the staggered and eclipsed conformations of propane, shown in the margin, are similar to those of ethane except that one of the H atoms has been replaced by a methyl group. The eclipsed conformation of propane has two C—H bond interactions and an interaction involving a C—H bond and a carbon–methyl bond. If we assume that each C—H bond interaction contributes 4.0 kJ mol^{-1} to the barrier to rotation, as was the case in ethane, then the interaction between the carbon– hydrogen bond and the carbon-methyl bond contributes $(13.6 - 2 \times 4.0) = 5.6$ kJ mol^{-1}. Thus, the interaction between a carbon–hydrogen bond and a carbon-methyl bond is slightly more repulsive than the interaction of two C—H bonds.



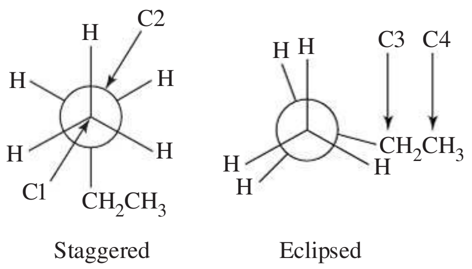
Staggered



Eclipsed

The next member in the homologous series is butane, $CH_3CH_2CH_2CH_3$. If we number the carbon atoms 1 through 4, then we have two distinct C—C bonds, C1—C2 and C2—C3, about which conformers can be formed. (The C3—C4 bond axis is equivalent to the C1—C2 bond axis because it does not matter whether we number the carbon atoms from left to right or right to left.) When the butane molecule is viewed along the C1—C2 bond, we obtain the following Newman projections for the staggered and eclipsed conformations:

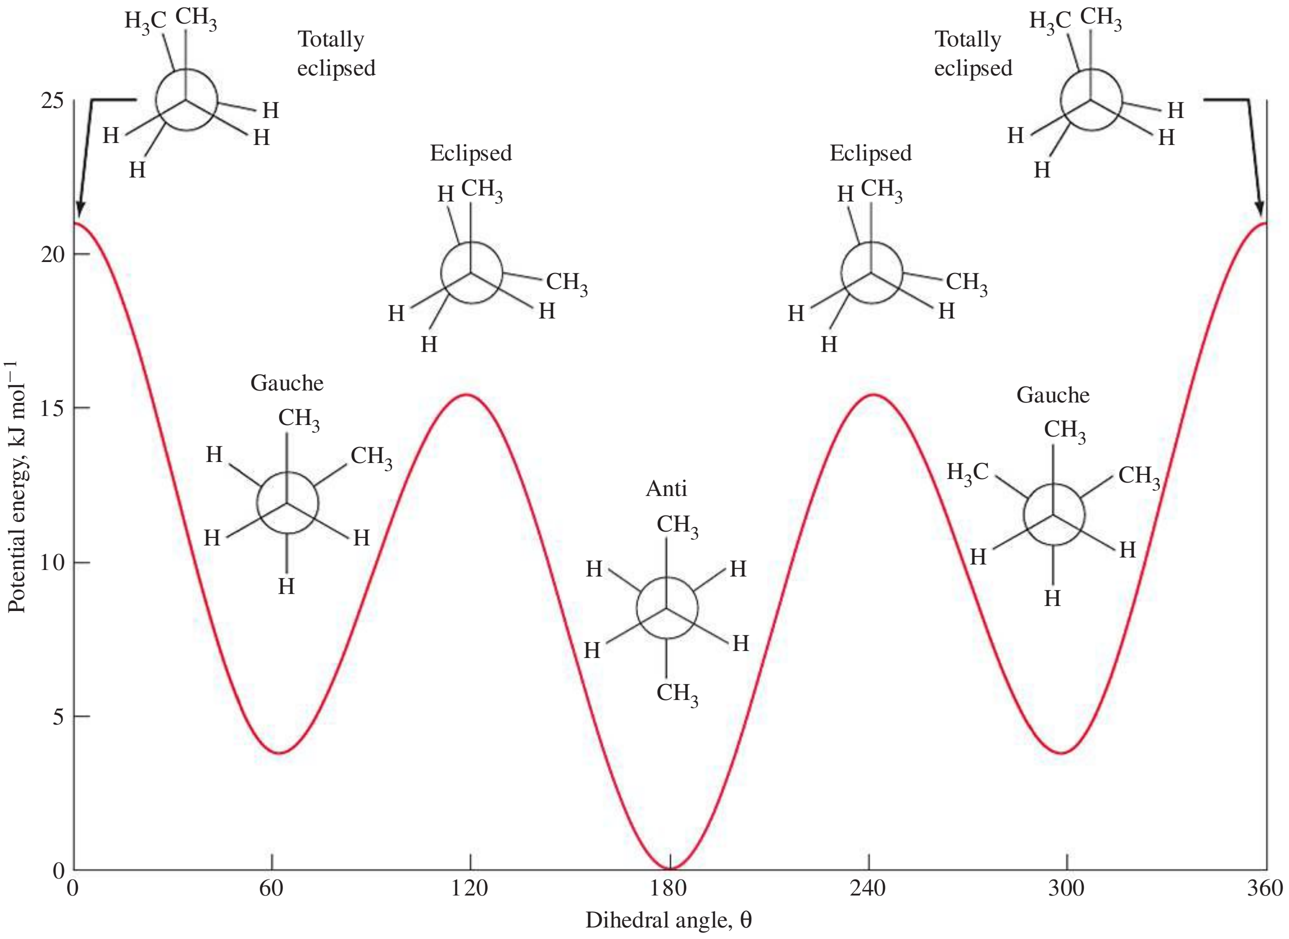
▶ When drawing Newman projections for molecules, it is customary to put the lower-numbered carbon atom at the front of the Newman projection.



26-5 CONCEPT ASSESSMENT

Will all the eclipsed conformers for rotation about the C1—C2 axis in butane have the same energy?

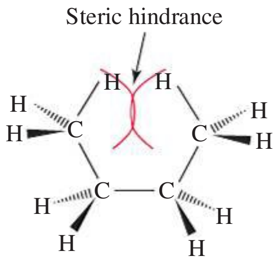
When the butane molecule is viewed along the C2—C3 bond, several eclipsed and staggered conformations can be identified (Figure 26-8). There



▲ FIGURE 26-8
Conformations and their potential energies of butane for rotation about the C2—C3 bond

are two distinct eclipsed conformations, eclipsed and totally eclipsed, and two distinct staggered conformations, anti and gauche. The totally eclipsed is highest in energy because in this conformation, the two largest constituents are eclipsed and interfere with each other, as suggested in Figure 26-9. The interference or crowding of large substituents is called *steric hindrance*.

Of the conformations shown in Figure 26-8, the anti conformation is the lowest in energy because the methyl groups are as far apart as possible. This conformation is called the **anti** conformation because the methyl groups are diagonally opposite each other. The other staggered conformation has the methyl groups to the left and right of each other and is called the **gauche** conformation. (*Gauche* is a French word meaning "left" or "awkward.")



▲ FIGURE 26-9
Steric hindrance in a totally eclipsed conformation of butane
In the totally eclipsed conformation, the two methyl groups interfere with each other.

EXAMPLE 26-4 Choosing the Most Stable Conformer of an Alkane

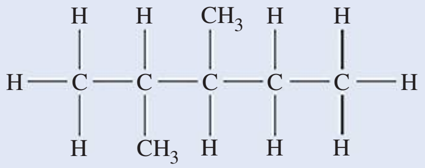
Draw the conformation of 2,3-dimethylpentane that is lowest in energy when the molecule is viewed along C2—C3 axis.

Analyze

We must first draw a structural diagram for the molecule and identify the C2—C3 axis and then draw a Newman projection corresponding to a view along the C2—C3 bond. The lowest energy structure is the one that minimizes the repulsions among the substituents.

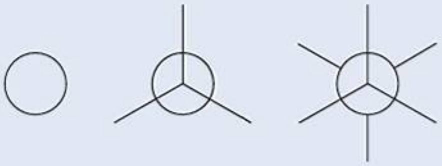
Solve

A structural diagram for 2,3-dimethylpentane is given here.

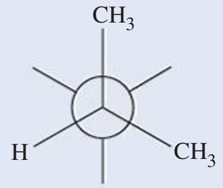


A hydrogen atom and two methyl groups are bonded to C2. Three different groups are bonded to C3: a hydrogen atom, a methyl group, and an ethyl group. The conformation of lowest energy is the one in which the alkyl groups are staggered. In addition to this, we should minimize the number of gauche interactions between the larger groups.

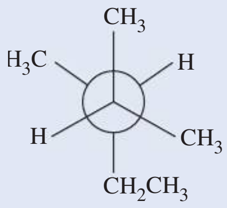
We must now construct a Newman projection corresponding to the view along the C2—C3 bond. First, we draw a circle to represent the rear carbon, and then we add lines for the bonds formed by the front carbon atom. Finally, we add lines for the bonds formed by the rear carbon atom.



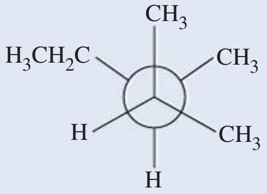
We are now ready to attach the groups to construct 2,3-dimethylpentane. Let us add two methyl groups and a hydrogen atom to the second carbon atom. Note it does not matter where we place the groups.



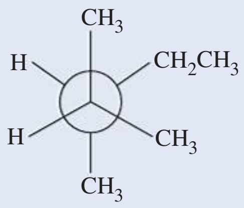
We must now add a hydrogen atom, as well as ethyl and methyl groups to the rear carbon. There are three possible staggered conformations:



(a)



(b)



(c)

(continued)

Which one of these conformations is lowest in energy? Conformation (a) has two gauche interactions, but conformations (b) and (c) have three such interactions. Therefore, conformation (a) has the lowest energy.

Assess

In solving this problem, we considered rotation about a particular carbon–carbon bond. Keep in mind that rotations about other carbon–carbon bonds also occur simultaneously, a complication that we will not consider.

PRACTICE EXAMPLE A: Draw Newman projections for the staggered conformations of 2-methylpentane when the molecule is viewed along the C1—C2 bond. Rank the conformations in order of increasing energy (from lowest to highest).

PRACTICE EXAMPLE B: Sketch a potential energy diagram for rotation about the C1—C2 axis in 1-chloropropane.

Preparation of Alkanes

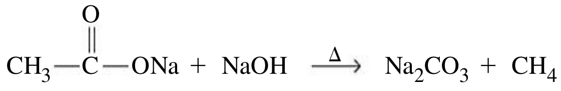
The chief source of alkanes is petroleum, as we describe at the end of this section, but several laboratory methods are also available for their preparation. In the presence of a metal catalyst such as Pt, Pb, or Ni, unsaturated hydrocarbons, whether containing double or triple bonds, may be converted to alkanes by the addition of H atoms to the multiple bond systems.

$$CH_2{=}CH_2 + H_2 \xrightarrow{\text{Pt, Pd, or Ni}} CH_3{-}CH_3 \qquad \textbf{(26.1)}$$

▶ Figure 23-3 gives a schematic representation of the role played by the catalyst in equation (26.1).

In another type of reaction, halogenated hydrocarbons react with alkali metals to produce alkanes of double the carbon content (equation 26.2). Finally, alkali metal salts of carboxylic acids can be fused with alkali metal hydroxides. Sodium carbonate and an alkane with one carbon fewer than the metal carboxylate are formed (equation 26.3).

$$2\,CH_3CH_2Br + 2\,Na \xrightarrow{\text{heat/pressure}} 2\,NaBr + CH_3CH_2CH_2CH_3 \qquad \textbf{(26.2)}$$



$$CH_3{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}ONa + NaOH \xrightarrow{\Delta} Na_2CO_3 + CH_4 \qquad \textbf{(26.3)}$$

Alkanes from Petroleum

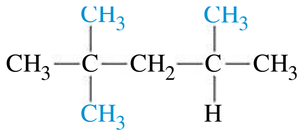
The lower molecular mass alkanes, methane and ethane, are found principally in natural gas. Propane and butane are found dissolved in petroleum; they can be extracted as gases and sold as liquefied petroleum gas (LPG). Higher alkanes are obtained by the fractional distillation of petroleum, a complex mixture of at least 500 compounds. The main petroleum fractions are listed in Table 26.4. (The liquid–vapor equilibrium principles that underlie fractional distillation were discussed on page 575.)

TABLE 26.4 Principal Petroleum Fractions

Boiling Range, °C	Composition	Fraction	Uses
Below 0	C_1 to C_4	Gas	Gaseous fuel
0–50	C_5 to C_7	Petroleum ether	Solvents
50–100	C_6 to C_8	Ligroin	Solvents
70–150	C_6 to C_9	Gasoline	Motor fuel
150–300	C_{10} to C_{16}	Kerosene	Jet fuel, diesel oil
Over 300	C_{16} to C_{18}	Gas–oil	Diesel oil, cracking stock
—	C_{18} to C_{20}	Wax–oil	Lubricating oil, mineral oil, cracking stock
—	C_{21} to C_{40}	Paraffin wax	Candles, wax paper
—	above C_{40}	Residuum	Roofing tar, road materials, waterproofing

Not all the hydrocarbons found in gasoline are equally desirable because some hydrocarbons burn more smoothly than others. (Explosive burning results in engine knocking.) The hydrocarbon *2,2,4-trimethylpentane*, a structural isomer of octane, has excellent engine performance, and it is given an octane rating of 100. *Heptane* has poor engine performance; its octane rating is 0. These two hydrocarbons serve as a reference system for rating gasoline. By identifying the composition of the *n*-heptane and 2,2,4-trimethylpentane (isooctane) mixture that matches the performance characteristics of the gasoline being tested, an octane rating can be assigned. For example, a gasoline that gives the same performance as a mixture of 87% 2,2,4-trimethylpentane and 13% heptane is assigned an octane number of 87. In general, branched-chain hydrocarbons have higher octane ratings (burn more smoothly) than their straight-chain counterparts.

▲ A catalytic cracking unit (cat cracker) at a petroleum refinery.



$$CH_3-\overset{\overset{\textstyle CH_3}{|}}{\underset{\underset{\textstyle CH_3}{|}}{C}}-CH_2-\overset{\overset{\textstyle CH_3}{|}}{\underset{\underset{\textstyle H}{|}}{C}}-CH_3$$

2,2,4-Trimethylpentane

Octane rating: 100

$$CH_3-CH_2-CH_2-CH_2-CH_2-CH_2-CH_3$$

n-Heptane

Octane rating: 0

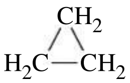
Gasoline obtained by fractional distillation of petroleum has an octane number of 50–55 and is not acceptable for use in automobiles, which require fuels with octane numbers near 90. Extensive modifications of the gasoline fraction are required. In *thermal cracking*, large hydrocarbon molecules (called *cracking stock*) are broken down into molecules in the gasoline range, and the presence of special catalysts promotes the production of branched-chain hydrocarbons. For example, the molecule $C_{15}H_{32}$ might be broken down into C_8H_{18} and C_7H_{14}. The process of *re-forming*, or isomerization, converts straight-chain to branched-chain hydrocarbons and other types of hydrocarbons having higher octane numbers. In thermal and catalytic cracking, some low-molecular mass hydrocarbons are rejoined into higher molecular mass hydrocarbons by a process known as *alkylation*.

◀ Not only do the processes of cracking, re-forming, and alkylation produce a higher grade of gasoline but they also increase the yield of gasoline obtained from crude oil.

The octane rating of gasoline can be further improved by adding antiknock compounds to prevent premature combustion. At one time, the preferred additive was tetraethyllead, $(C_2H_5)_4Pb$. Lead additives have been phased out of gasoline in most countries because lead is toxic, and substitutes such as the oxygenated hydrocarbons methanol and ethanol are used instead.

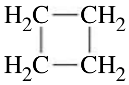
26-3 Cycloalkanes

Alkanes in chain structures have the formula C_nH_{2n+2}. However, alkanes can also exist in ring, or cyclic, structures; such alkanes are called *cycloalkanes*. For simple cycloalkanes, we can think of the rings as having formed by the joining of the two ends of a straight-chain alkane after the elimination of an H atom from each end. Simple cycloalkanes have the formula C_nH_{2n}. Here are a few examples:



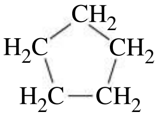
Cyclopropane

C_3H_6



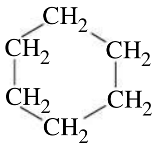
Cyclobutane

C_4H_8



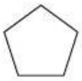
Cyclopentane

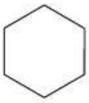
C_5H_{10}

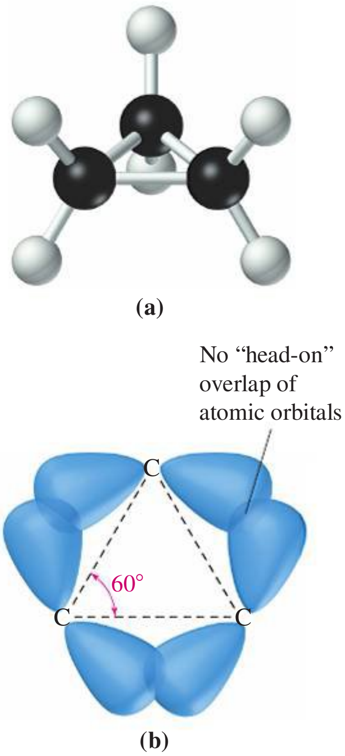


Cyclohexane

C_6H_{12}



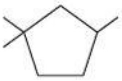




▲ FIGURE 26-10
Ring strain in cyclopropane
(a) Ball-and-stick model.
(b) Valence-bond picture of cyclopropane using sp^3 hybrid orbitals, which leads to poor overlap of the orbitals and hence weak bonds.

The line-angle representations shown at the bottom of page 1161 might lead you to believe that the carbon atoms in cycloalkanes all lie in the same plane. However, this is not generally the case. As we will soon see, cyclopropane is the only cycloalkane in which the carbon atoms form a planar ring.

We can use the nomenclature rules on page 1151 to name a cycloalkane having substituent groups. For example, we would name the following compound 1,1,3-trimethylcyclopentane:



Ring Strain in Cycloalkanes

Some discussion of the bonding in cycloalkanes is warranted because, in these molecules, the sp^3-hybridized carbons do not necessarily form bonds that are 109.5° apart. For example, the C—C—C bond angles in cyclopropane are only 60° (Fig. 26-10). Because the bond angle in cyclopropane is much smaller than the ideal bond angle of 109.5°, the cyclopropane molecule is "strained." As illustrated in Figure 26-10(b), the carbon sp^3 orbitals in propane do not overlap as extensively as they do in straight-chain alkanes. As a result of the poor orbital overlap, the C—C bonds in cyclopropane are substantially weaker than they are in propane and other straight-chain alkanes, and cyclopropane is considerably more reactive than a straight-chain alkane.

We can use heats of combustion to estimate the amount of ring strain in cycloalkanes. The heats of combustion of propane, butane, pentane, and hexane are given in Table 26.5 along with those of the corresponding cycloalkanes. For the straight-chain alkanes, the heat of combustion changes by about 658 kJ mol^{-1} with each CH_2 group added. This suggests that each CH_2 group contributes, on average, 658 kJ mol^{-1} to the heat of combustion. The formula of a cycloalkane may be written as $(CH_2)_n$ and, if we assume that the C—C bonds that link together CH_2 groups in cycloalkanes are the same as they are in straight-chain alkanes, then the heat of combustion of a cycloalkane should be about $-n \times 658$ kJ mol^{-1}. The energy associated with ring strain is released as heat when the compound is burned and thus, the heat of combustion is more negative than expected. The estimated and experimental heats of combustion for a few cycloalkanes are given in Table 26.5. The difference between the estimated and experimental values provides a measure of the ring strain in the cycloalkanes, and these values are also shown in the table. The data in Table 26.5 show that, as we proceed from cyclopropane to cyclohexane, the amount of ring strain decreases. Interestingly, the cyclohexane ring is essentially free of ring strain. We will soon see why.

The data in Table 26.5 show that cyclopropane and cyclobutane experience a significant amount of ring strain. However, the *ring strain per CH_2 group* is

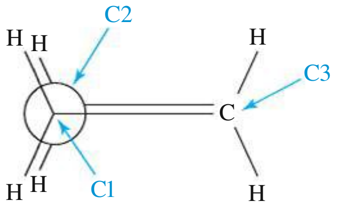
▶ The C—C bond energy in cyclopropane is about 289 kJ mol^{-1}. This is substantially smaller than the C—C bond energy of 347 kJ mol^{-1} given in Table 10.3.

TABLE 26.5 Heats of Combustion and Ring Strain in Some Cycloalkanes (All Values in kJ mol^{-1})

Alkane	Experimental ΔH°_{comb}	Contribution to ΔH°_{comb} from Each Additional CH_2 Group	Cycloalkane	Experimental ΔH°_{comb}	Estimated ΔH°_{comb}[b]	Ring Strain[c]
propane	−2220		cyclopropane	−2092	−1974	118
butane	−2877	−657[a]	cyclobutane	−2744	−2632	112
pentane	−3536	−659	cyclopentane	−3320	−3290	30
hexane	−4194	−658	cyclohexane	−3948	−3948	0

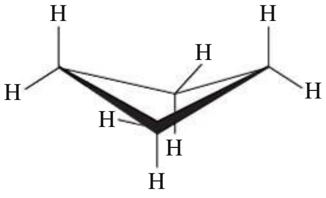
[a] The difference between successive values of ΔH°_{comb} is the contribution to ΔH°_{comb} made by adding another CH_2 group. For example, ΔH°_{comb} (butane) − ΔH°_{comb} (propane) = −657 kJ mol^{-1}.
[b] If there is no ring strain, then the heat of combustion of a cycloalkane should be $-n \times 658$ kJ mol^{-1}.
[c] The ring strain is equal to the difference between the estimate and experimental values of ΔH°_{comb}.

substantially higher in cyclopropane (39 kJ mol^{-1}) than it is in cyclobutane (28 kJ mol^{-1}). The cyclopropane ring is strained not only because of poor orbital overlap but also because the carbon–hydrogen bonds in this molecule are eclipsed. This is most evident from the Newman projection of cyclopropane, which is shown in Figure 26-11.

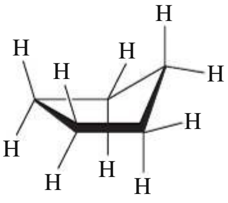


▲ FIGURE 26-11
Newman projection for cyclopropane
The carbon atom in front (C1) and the carbon atom in the rear (C2) are both bonded to the other carbon atom (C3). The H—C1 and H—C2 bonds are eclipsed.

In cyclopropane, the carbon atoms lie in the same plane, but in other cycloalkanes, they do not. For example, both the cyclobutane and the cyclopentane molecules buckle slightly to give rings that are puckered rather than planar, as shown below.



Cyclobutane



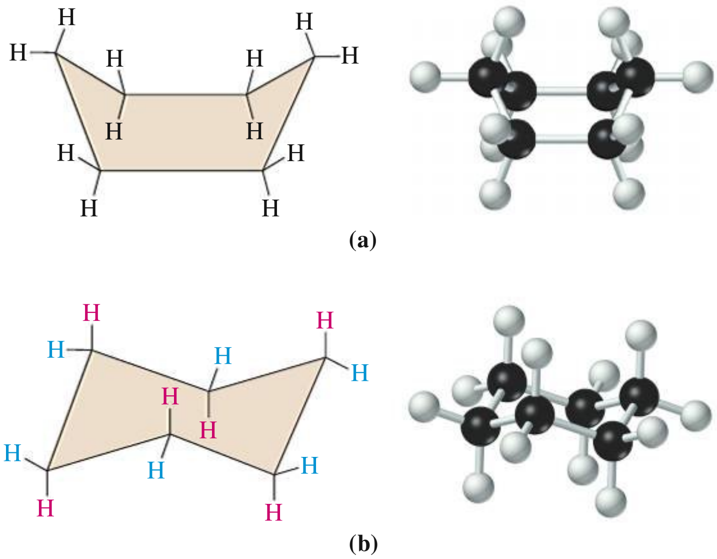
Cyclopentane

When these molecules buckle, some or all of the hydrogen atoms move slightly out of the totally eclipsed conformation, relieving repulsion associated with the eclipsing of carbon–hydrogen bonds but at the expense of decreasing the already strained C—C—C bond angles even further.

For cyclohexane, two conformations of the molecules are important. They are shown as ball-and-stick models in Figure 26-12. These are called the *boat* and the *chair conformations*. The boat conformation is less stable (29 kJ mol^{-1} higher in energy) than the chair conformation. There are other conformations of cyclohexane, but we will not discuss them. You may encounter them in more advanced organic chemistry courses.

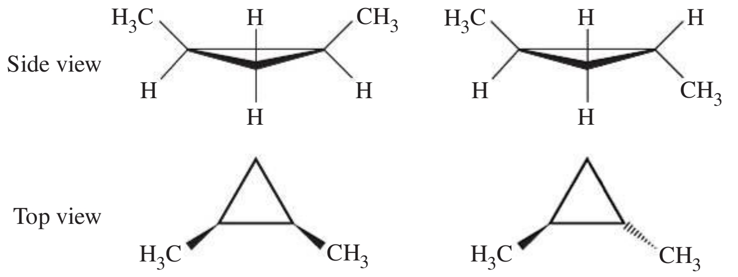
Cis–Trans Isomerism in Disubstituted Cycloalkanes

The ring in a cycloalkane has two distinct faces, and the substituents bonded to a particular carbon atom are adjacent to opposite faces of the ring. Let's consider, for example, the ball-and-stick model of cyclopropane, which was shown in Figure 26-10. If we focus on the hydrogen atoms bonded to the rearmost carbon, for example, then we see that one of the hydrogen atoms is above the plane of the three carbon atoms and the other is below the plane. Stated another way, one hydrogen atom is adjacent to the upper face and the other is adjacent to the lower face. If hydrogen atoms



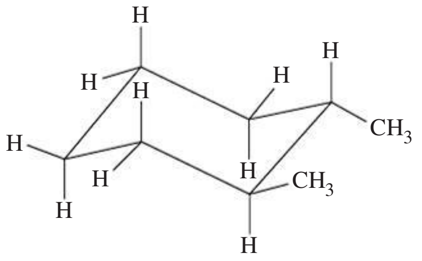
◀ FIGURE 26-12
Two important conformations of cyclohexane
(a) Boat form. **(b)** Chair form. The H atoms extending laterally from the ring—equatorial H atoms—are shown in blue. The H atoms projecting above and below the ring—axial H atoms—are in red.

on different carbon atoms are replaced by other substituents, as is the case in 1,2-dimethylcyclopropane or 1,2-dimethylhexane, then various isomers are possible. The *cis* and *trans* isomers of 1,2-dimethylcyclopropane are shown below. (*cis* is a Latin word meaning "on this side"; *trans* is Latin for "across.")

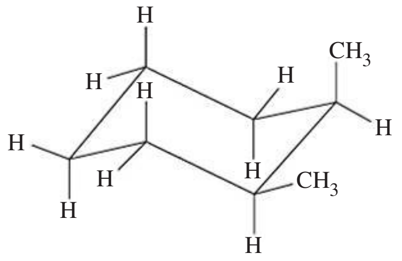


cis-1,2-dimethylcyclopropane *trans*-1,2-dimethylcyclopropane

The *cis* and *trans* isomers of 1,2-dimethylcyclohexane are



trans-1,2-dimethylcyclohexane

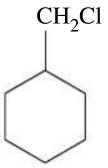


cis-1,2-dimethylcyclohexane

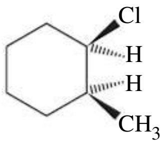
In the *cis* isomers, the two substituents are adjacent to the same face of the ring and in the *trans* isomers they are adjacent to opposite faces. To convert the *cis* isomer into the *trans* isomer (or vice versa), bonds must be broken and reformed. ***cis–trans* isomerism** is only one type of a more general kind of isomerism known as **stereoisomerism**. (This term is derived from the Greek word *stereos*, meaning "solid, or three-dimensional, in nature"). For stereoisomers, the number and types of atoms and bonds are the same, but certain atoms are oriented differently in space.

▶ Conformers are interconverted by rotation about bonds. However, stereoisomers can be interconverted only by breaking and reforming bonds.

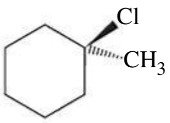
For disubstituted cycloalkanes, many isomers are possible. Consider chloromethylcyclohexane, for example. It has eight isomers in total, three of which are shown below:



Chloromethylcyclohexane



cis-1-chloro-2-methylcyclohexane



1-chloro-1-methylcyclohexane

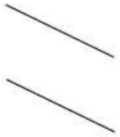
26-6 CONCEPT ASSESSMENT

Draw dashed and solid wedge line structures for the *trans* isomers of chloromethylcyclohexane.

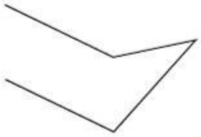
A Closer Look at Cyclohexane

The bond angles are approximately 109.5° in both the chair and the boat forms of cyclohexane. However, the chair form of cyclohexane is slightly lower in energy. Why is this? To answer this question, we will first describe how to draw the chair form of cyclohexane and then use a Newman projection to provide the insight needed.

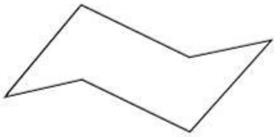
1. Draw two parallel lines that are slightly tilted.



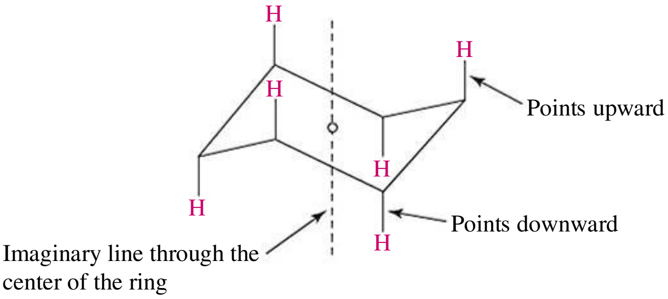
2. Connect the lower ends with a cap that points upward.



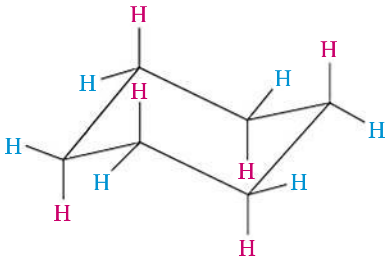
3. Connect the upper ends with a cap that points downward.



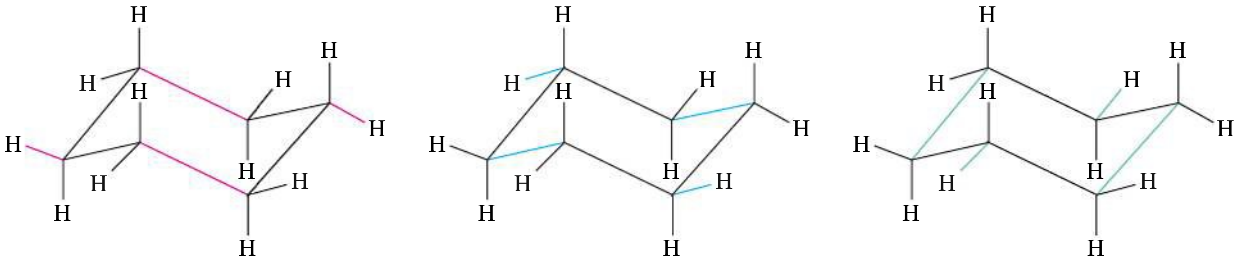
4. Add an axial hydrogen atom to each carbon atom. The bonds to the axial hydrogen atoms point up when the carbon atom points upward, and down when the carbon atom points downward. They are parallel to an imaginary line that passes through the center of the cyclohexane ring.



5. Add an equatorial hydrogen atom to each carbon atom. The bonds to the equatorial hydrogen atoms point sideways and complete the tetrahedral arrangement of bonds around each carbon atom. In this diagram, the axial hydrogens are shown in red and the equatorial hydrogens are shown in blue.

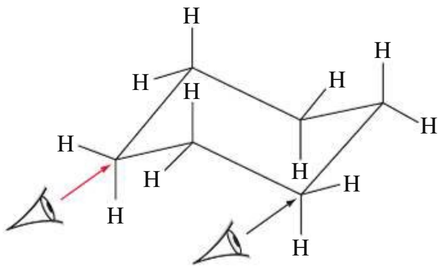


As we can see from these drawings, there are two types of hydrogen atoms: *axial* and *equatorial*. The bonds to the axial hydrogen atoms are directed vertically up or down and are parallel to an imaginary axis that passes through the center of the ring. The bonds to the equatorial hydrogen atoms are directed sideways from the ring. As we move around the ring, the axial hydrogen atoms alternate such that one points upward and the next points downward. There is a similar alternation for the equatorial hydrogen atoms. For the equatorial hydrogen atoms, it is instructive to note which pairs of C—H and C—C bonds are parallel.

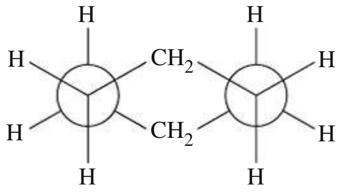


It is possible to construct a Newman projection for the chair form of cyclohexane if we view the molecule along a pair of C—C bonds that are parallel to each other, as suggested below:

▶ Building a molecular model will help you visualize many of the concepts being discussed in this section. Build a model of cyclohexane to convince yourself that the same Newman projection is obtained when the molecule is viewed along the other two pairs of parallel C—C bonds.



Line structure

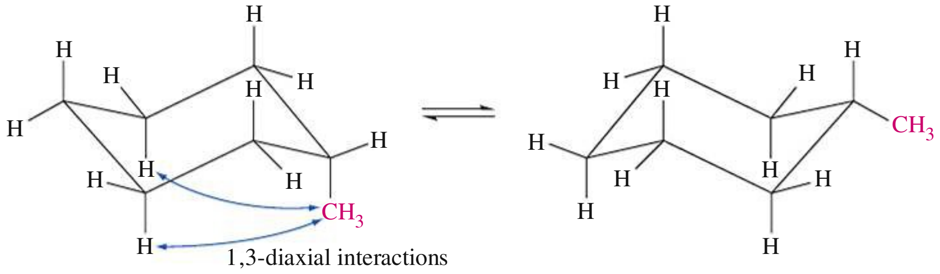


Newman projection

The Newman projection above shows that the carbon–hydrogen bonds are staggered. Some of the carbon–hydrogen bonds in the boat form are eclipsed, and consequently the boat form is higher in energy (and is less stable) than the chair form.

The cyclohexane molecule interconverts rapidly between two stable chair conformations, as suggested in Figure 26-13. This interconversion is called a ring flip. When the ring flips from one chair conformation to another, every axial hydrogen in one conformation becomes an equatorial hydrogen in the other conformation, and vice versa. At room temperature, the cyclohexane ring undergoes approximately 100,000 ring flips per second.

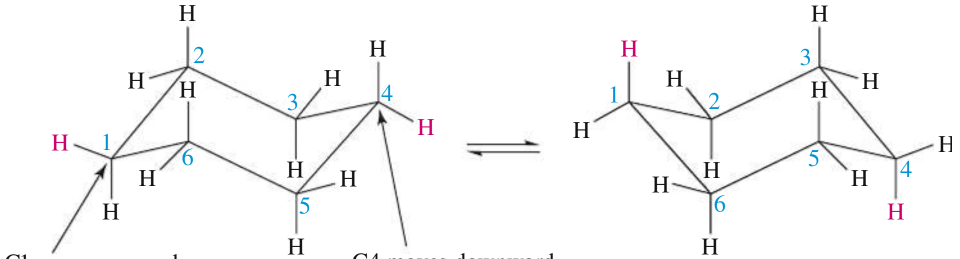
The two chair conformations of cyclohexane shown in Figure 26-13 are equivalent and have exactly the same energy. However, when H atoms in cyclohexane are replaced by substituents, the chair conformations no longer have the same energy. Consider, for example, the following chair conformations for methylcyclohexane:



Less stable

More stable

The conformer with the methyl group in the equatorial position is of lower energy than the one with the methyl group in the axial position because, when



▲ FIGURE 26-13

The interconversion of two chair conformations in cyclohexane

In the figure, two of the H atoms are shown in red to emphasize that when the cyclohexane ring converts from one chair conformation to another, the equatorial hydrogen atoms are converted into axial hydrogen atoms and vice versa. The interconversion of the two chair forms proceeds through other conformations, including the boat form.

the methyl group is in an axial position, it interacts simultaneously (blue arrows) with two axial H atoms. Each interaction is called a *1,3-diaxial interaction* because it involves a substituent on the carbon atom that is numbered C3, assuming the carbon atom bonded to the methyl group is C1.

26-7 CONCEPT ASSESSMENT

If you could measure the individual heats of combustion of axial and equatorial methylcyclohexane, which conformer would burn more exothermically?

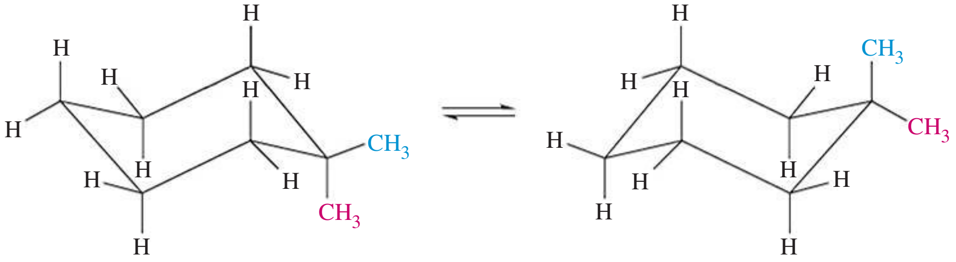
The energy differences between the axial and the equatorial forms of several mono-substituted cyclohexanes have been measured. Some of these energy differences are given in Table 26.6. Table 26.6 shows that for alkyl groups the energy difference between the axial and equatorial forms increases with the size of the group, a direct consequence of increasingly unfavorable steric interactions. This effect is particularly pronounced in *tert*-butylcyclohexane. Only about 0.01% of these molecules exist as the axial conformer at room temperature. The molecule is effectively locked with the *tert*-butyl group in the equatorial position!

TABLE 26.6 Gibbs Energy Differences between Axial and Equatorial Conformers of Mono-substituted Cyclohexanes

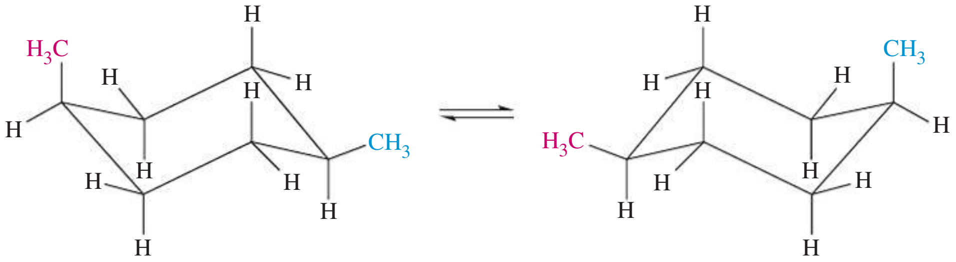
Substituent	$\Delta G°$, kJ mol^{-1}
$-H$	0
$-CH_3$	7.1
$-CH_2CH_3$	7.3
$-CH(CH_3)_2$	9.2
$-C(CH_3)_3$	21

If there are two substituents, they compete for the equatorial position. In general, the conformation of lowest energy has the bulkier group in the equatorial position.

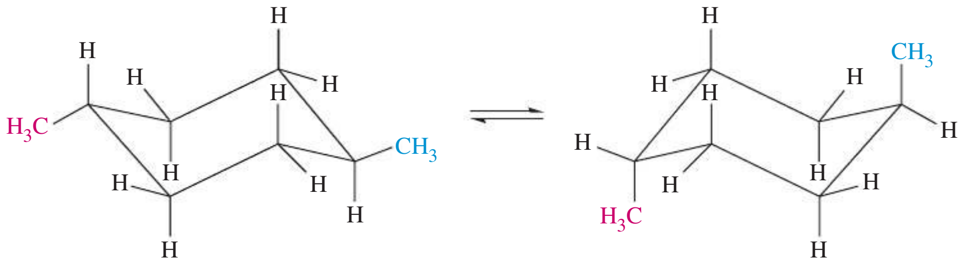
Let us compare some isomers of dimethylcyclohexane. In 1,1-dimethylcyclohexane, one methyl group is axial and the other equatorial. A ring flip produces a conformation of equal energy, as shown below:



Now consider *cis*-1,4-dimethylcyclohexane. Both of the chair conformations shown below have one axial methyl group and one equatorial group. The two conformations have the same energy:



Unlike the *cis* isomer, the *trans* isomer can exist in one of two different chair conformations. One conformation has two axial methyl groups and the other has two equatorial groups, as shown below:



The conformation that has both methyl groups in equatorial positions is 14.2 kJ mol^{-1} lower in energy than the conformation that has the methyl groups in axial positions. This energy difference is twice that given in Table 26.6 for methylcyclohexane.

26-8 CONCEPT ASSESSMENT

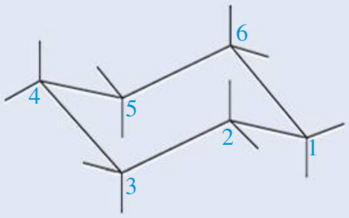
Which chair conformation of *cis*-1-fluoro-4-methylcyclohexane is lower in energy?

EXAMPLE 26-5 Predicting Which Conformer of a Disubstituted Cycloalkane Is Lowest in Energy

Draw the lowest energy conformation of *cis*-1,3-dimethylcyclohexane.

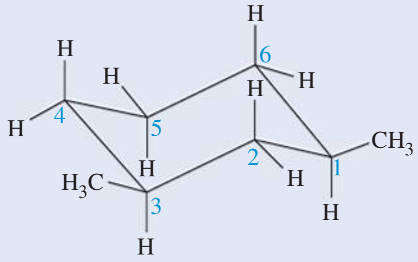
Analyze

First, we draw a cyclohexane ring showing both the axial and the equatorial bonds but without the substituents added to the ring. Then, we consider the placement of the substituents. A useful tip is to realize that when the carbon atoms in a cyclohexane ring are numbered, there is a relationship between the bonds on the odd- and even-numbered carbon atoms. When the odd-numbered carbons have their *up* bonds axial, the even-numbered carbon atoms have their *down* bonds axial. When the odd-numbered carbons have their *up* bonds equatorial, the even-numbered carbons have their *down* bonds equatorial. The relationship is illustrated in the diagram below:



Solve

We are dealing with a *cis* isomer, and so both methyl groups are adjacent to the same face of the ring. This is possible only if the two methyl groups are bonded to the two carbon atoms with both bonds up or both bonds down. The conformation of lowest energy will be the one that has the methyl groups in the equatorial positions.



Assess

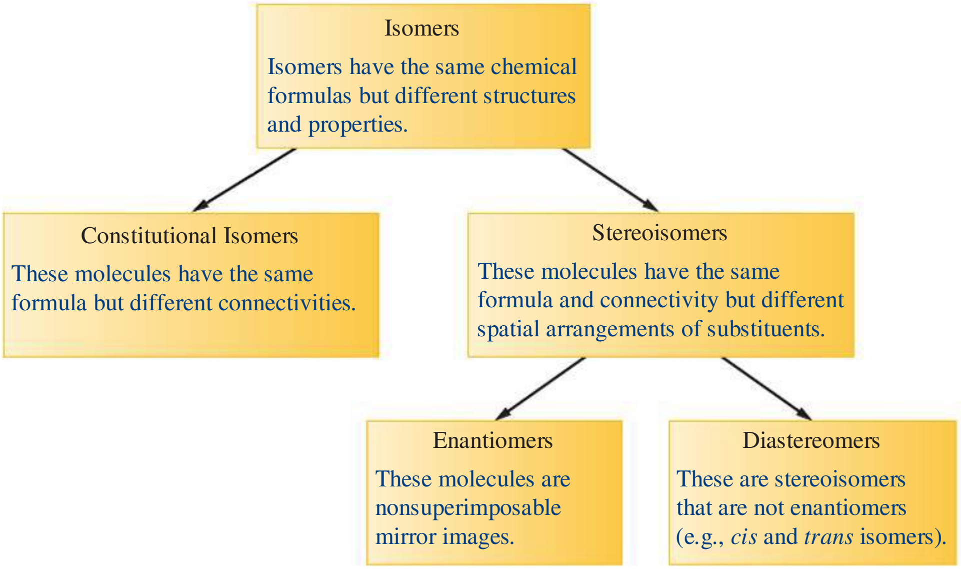
If the molecule above undergoes a ring flip, the methyl groups will be in the axial positions and the resulting conformation will be higher in energy.

PRACTICE EXAMPLE A: Draw the lower energy conformation of *trans*-1,4-dimethylcyclohexane.

PRACTICE EXAMPLE B: Draw the lower energy conformation of *cis*-1-*tert*-butyl-2-methylcyclohexane.

26-4 Stereoisomerism in Organic Compounds

In Figure 26-14, we have summarized different forms of isomerism that we encounter in organic chemistry. We have already discussed constitutional isomerism and learned about one form of stereoisomerism, namely *cis–trans*



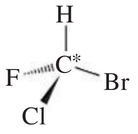
Isomers
Isomers have the same chemical formulas but different structures and properties.
Constitutional Isomers
These molecules have the same formula but different connectivities.
Stereoisomers
These molecules have the same formula and connectivity but different spatial arrangements of substituents.
Enantiomers
These molecules are nonsuperimposable mirror images.
Diastereomers
These are stereoisomers that are not enantiomers (e.g., *cis* and *trans* isomers).

◀ FIGURE 26-14
Isomerism summarized

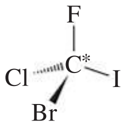
isomerism in cycloalkanes. As illustrated in Figure 26-14, *cis–trans* isomers are also known as **diastereomers**. In this section we will focus on another form of stereoisomerism—**enantiomerism**—which arises when an organic compound has an asymmetric carbon. An **asymmetric** carbon (also called a **chiral** carbon) is one that is bonded to four different groups. Molecules with an asymmetric carbon exist as stereoisomers that cannot be interconverted without breaking and reforming bonds. We will see (in Chapter 28) that molecules with asymmetric carbon atoms figure prominently in biochemistry.

Chirality

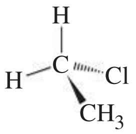
We saw in Chapter 24 that a solution of an optically active compound can rotate the plane of polarized light. The requirement for optical activity is that the molecule be asymmetric—that is, its mirror image cannot be superimposed on the original molecule. This situation can arise at a tetrahedral C atom when all four groups attached to the C atom are different. Consider the molecule 3-methylhexane shown in Figure 26-15. The illustration shows that there are two nonsuperimposable isomers of 3-methylhexane related as mirror images. The two isomers are said to be *enantiomers*. A molecule that is not superimposable on its mirror image is said to be *chiral*. Compounds whose structures are superimposable on their mirror images are **achiral**. Examples of chiral and achiral molecules are shown here, using the dashed and solid wedge line notation:



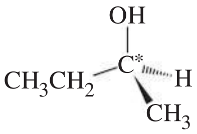
Chiral



Chiral



Achiral

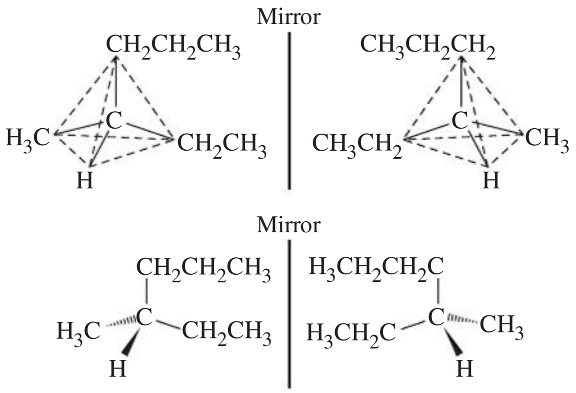


OH
CH3CH2
C*
H
CH3
Chiral

All the chiral molecules shown contain an atom that is connected to four different substituent groups. The C atom to which the four different groups are attached is said to be **asymmetric**, or a **stereocenter**. Centers of this type are sometimes denoted by an asterisk. Molecules with one stereocenter are always chiral. As we will see in Chapter 28, molecules incorporating more than one stereocenter need not be chiral, and many chiral molecules occur in nature. As described in Chapter 27, the existence of chirality can play an important role in establishing some reaction mechanisms.

KEEP IN MIND

that a solution of one enantiomer rotates the plane of polarized light in one direction whereas a solution of the other enantiomer rotates the light in the opposite direction. With a 50:50 mixture of the two enantiomers—a racemic mixture—no rotation of the plane of polarized light is observed.



▶FIGURE 26-15
Nonsuperimposable mirror images of 3-methylhexane
Notice in the diagram that we have adopted the convention used by organic chemists in drawing chiral centers: The groups attached to the central carbon in the plane of the paper are connected with solid lines, the group in front of the plane of the paper is attached by a solid wedge, and the group behind the plane of the paper is indicated by a dashed wedge.

EXAMPLE 26-6 Identifying a Chiral Molecule

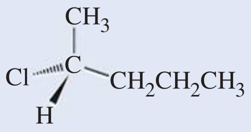
Predict whether either 2-chloropentane or 3-chloropentane is chiral.

Analyze

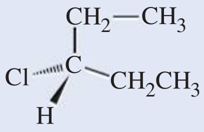
To decide whether a molecule is chiral, we look for a C atom that has four different groups attached.

Solve

The two compounds are shown below.



2-chloropentane



3-chloropentane

We see that 2-chloropentane contains a C atom that has four different groups attached; hence, 2-chloropentane is chiral. However, 3-chloropentane does not have such a C atom; its structure is identical to its mirror image and thus, 3-chloropentane is achiral.

Assess

In drawing the structures, we focused only on the carbons to which the Cl atoms were attached. All the other carbons are bonded to at least two H atoms (two groups are the same) and cannot possibly be chiral

PRACTICE EXAMPLE A: Which of the following chlorofluorohydrocarbons is chiral: **(a)** $CF_3CH_2CCl_3$; **(b)** $CF_2HCHFCCl_3$; **(c)** $CClFHCHHCCl_2F$?

PRACTICE EXAMPLE B: Which of the following chloroalcohols is chiral: **(a)** $CH_2ClCH_2CH_2OH$; **(b)** $CH_2ClCH(OH)CH_3$; **(c)** $CH(OH)ClCH_2CH_3$?

26-9 CONCEPT ASSESSMENT

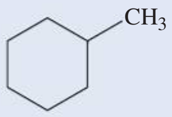
How many chiral centers are there in 2,3-bromopentane? How many different stereoisomers are there?

EXAMPLE 26-7 Identifying Chiral Carbon Atoms in Cycloalkanes

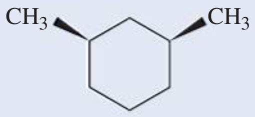
Identify any chiral carbon atoms in the molecules to the right.

Analyze

A carbon atom is chiral if it is bonded to four different groups. To determine whether a carbon



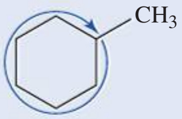
Methylcyclohexane



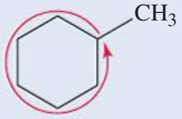
cis-1,3-dimethylcyclohexane

atom in a ring structure is chiral, we must go around the ring in each direction (clockwise and counterclockwise) to see if there is a point of difference. If there is a point of difference, then the carbon atom is chiral.

Solve

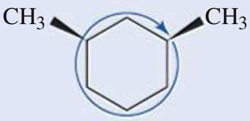


Clockwise path

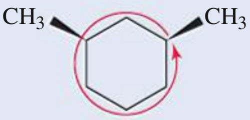


Counterclockwise path

When considering carbon atoms in the rings of these molecules, we need only focus on carbon atoms where hydrogen atoms have been replaced by other substituents. If there is no substituent, then the carbon atom has two identical groups (two hydrogen atoms) and thus, cannot be chiral. Thus, for methylcyclohexane, we focus only on C1, the carbon bonded to the methyl substituent. The clockwise and counterclockwise paths starting from C1 have identical constitutions ($—CH_2CH_2CH_2CH_2CH_2—$) and so, we conclude that C1 in methylcyclohexane is not chiral.



Clockwise path



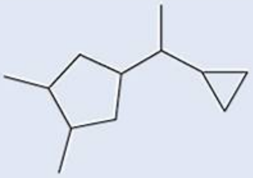
Counterclockwise path

When we compare the clockwise and counterclockwise paths, starting from C1, in 1,3-dimethylcyclohexane, we notice that there is a point of difference. The constitution of the clockwise path (blue) is $—CH_2CH_2CH_2CH(CH_3)CH_2—$ and that of the counterclockwise path (red) is $—CH_2CH(CH_3)CH_2CH_2CH_2CH_2—$. The two paths are different; thus, C1 is chiral. Following similar reasoning, we find that C3 is also chiral. Thus, in cis-1,3-dimethylcyclohexane, C1 and C3 are chiral.

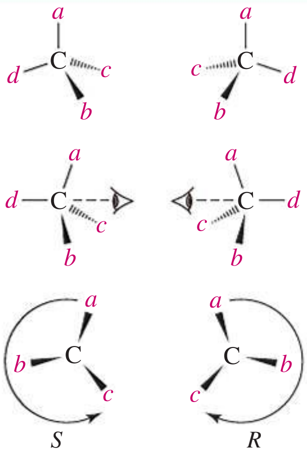
Assess

In most of the examples we have considered so far, there has been only one chiral atom per molecule. Such molecules are optically active. In this example, we see that 1,3-dimethylcyclohexane has two chiral carbon atoms. A molecule with two or more chiral carbon atoms may or may not be optically active. Optical activity of molecules containing two or more chiral atoms is discussed in advanced organic chemistry courses.

PRACTICE EXAMPLE A: Identify the chiral carbon atoms in the molecule shown in the diagram on the right.



PRACTICE EXAMPLE B: How many chiral atoms are there in 1,1,4-trimethylcyclohexane?

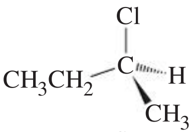


▲ FIGURE 26-16
Assignment of *R* and *S* configuration at a tetrahedral stereocenter
The group of lowest priority is placed as far away from the viewer as possible.

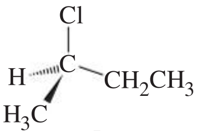
Naming Enantiomers: The *R*, *S* System of Nomenclature

To differentiate two enantiomers, we need a system of nomenclature that indicates the arrangement or configuration of the four groups about the chiral center. Such a system was developed by three chemists, R. S. Cahn, C. Ingold, and V. Prelog. The first step is to rank the four substituents in order of decreasing priority. The rules for assigning priorities will be described shortly.

Suppose that in the hypothetical compound *Cabcd*, substituent *a* has the highest priority, *b* the second highest, *c* the third highest, and *d* the lowest. Now position the molecule (mentally, on paper, or with a model set) so that the lowest priority substituent is as far away from the viewer as possible (Fig. 26-16). This procedure results in two possible arrangements for the remaining substituents (one for each enantiomer). In the ***R*, *S* system**, if the sequence from *a* to *b* to *c*, as viewed toward the substituent of lowest priority, is clockwise, the configuration of the stereocenter is named *R* (*rectus*, Latin, meaning right). Conversely, if the sequence is counterclockwise, the stereocenter is named *S* (*sinister*, Latin, meaning left). The symbol (*R*) or (*S*) is added as a prefix to the name of the chiral compound, as in (*R*)-2-chlorobutane and (*S*)-2-chlorobutane, shown below. A racemic mixture of the enantiomers is designated (*R*, *S*) as in (*R*, *S*)-2-chlorobutane.



(*S*)

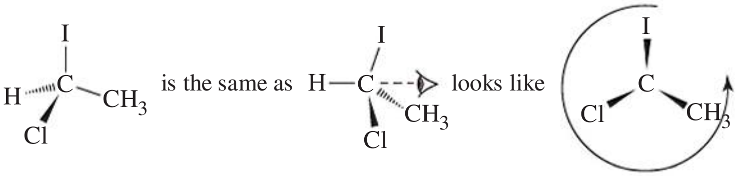


(*R*)

Rules for Assigning Priorities to Substituents In order to apply the *R*, *S* nomenclature to a stereocenter, we must first describe how the priorities are assigned to substituents. When looking at the atoms attached directly to the stereocenter, the rules devised by Cahn, Ingold, and Prelog are as follows:

▶ Strictly speaking, the parameter that decides priority is atomic mass, not atomic number. However, atomic mass increases as the atomic number increases, so unless we are comparing isotopes of the same element (same atomic number, different atomic masses), we can assign priorities by focusing on atomic number.

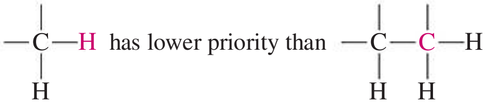
Rule 1. A substituent atom of higher atomic number takes precedence over one of lower atomic number. Consider the enantiomer of 1-chloro-1-iodoethane shown below.



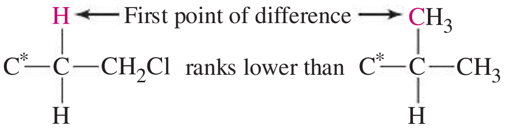
Priority I > Priority Cl > Priority C
(*S*)-1-chloro-1-iodoethane

The order of priority, as viewed toward the H atom (which has the lowest priority), is counterclockwise. Therefore the enantiomer is (*S*)-1-chloro-1-iodoethane.

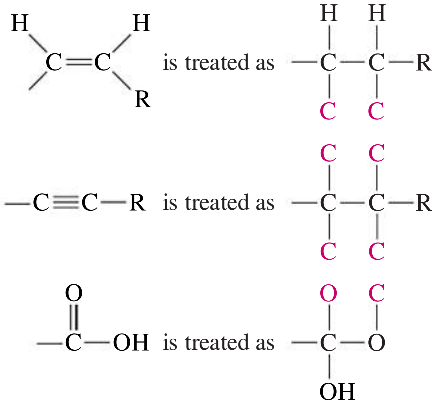
Rule 2. If two substituent atoms attached to the stereocenter have the same priority, proceed along the two substituent chains until a point of difference is reached. The atom of higher atomic number at this point establishes the priority. Thus, an ethyl group takes priority over a methyl group for the following reason. Although at the point of attachment to the stereocenter each substituent has a C atom, equal in priority, beyond these C atoms the methyl group has an H atom and the ethyl group has a higher-priority C atom.



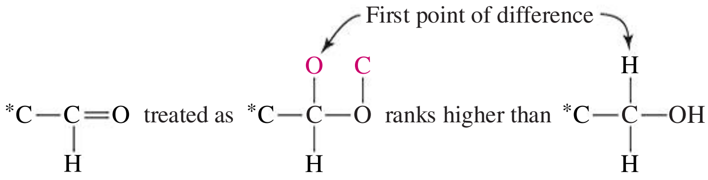
It is important to understand that the decision on priority is made at the *first* point of difference along otherwise similar substituent chains. When that point has been reached, the constitution of the remainder of the chain is immaterial.



Rule 3. Double bonds and triple bonds are treated as if they were single, and the atoms in them are duplicated or triplicated at each end by the particular atoms at the *other end of the multiple bond*. For example,



Note that the atoms shown in red are added simply for the purpose of assigning priority to the groups containing a multiple bond; they are *not* really there! To illustrate, the —CH_2OH group has lower priority than —CHO.

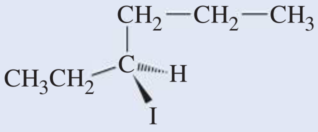


The assignment of priorities and configuration of a chiral center is illustrated in Example 26-8.

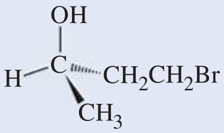
EXAMPLE 26-8 Assignment of Priorities and Configuration of a Chiral Center

Name each of the following compounds, including the assignment of configuration.

(a)



(b)



Analyze

To assign the configuration at the stereocenter, we must first assign the priorities of the substituents. Then we determine the *R* or *S* configuration by viewing the molecule toward the atom of lowest priority.

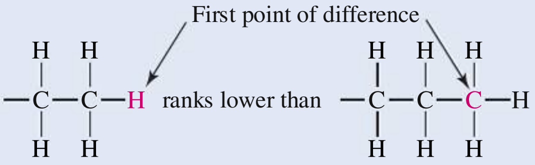
Solve

(a) This molecule is 3-iodohexane with C3 as the chiral center. The order of priorities of atoms attached to C3 is

$$I > C\,(\text{ethyl}) = C\,(\text{propyl}) > H$$

(continued)

In order to decide the ranking of the ethyl group relative to the propyl group, we go to the first point of difference in the chains of these substituents.

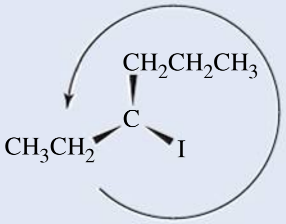


First point of difference
ranks lower than

We see that the propyl group ranks higher than the ethyl group, so the order of priorities is

$$\mathrm{I} > \mathrm{C}\,(\text{propyl}) > \mathrm{C}\,(\text{ethyl}) > \mathrm{H}$$

Viewing the molecule toward the lowest priority H atom, we see that the priorities decrease in a counterclockwise manner, so the configuration at the stereo center is *S*. The complete name of the molecule is (*S*)-3-iodohexane.

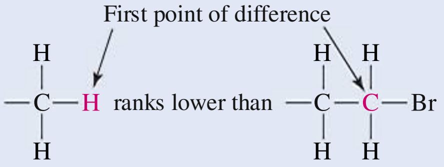


CH$_2$CH$_2$CH$_3$
C
CH$_3$CH$_2$
I

(b) This molecule is 4-bromo-2-butanol, with C2 as the chiral center. The order of priorities of atoms attached to C2 is

$$\mathrm{O} > \mathrm{C}\,(\text{bromoethyl}) = \mathrm{C}\,(\text{methyl}) > \mathrm{H}$$

In order to decide the ranking of the bromoethyl group relative to the methyl group, we go to the first point of difference in the chains of these substituents.

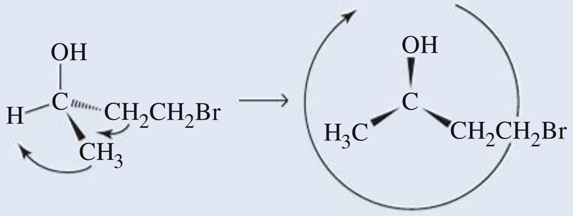


First point of difference
ranks lower than

We see that the bromoethyl group ranks higher than the methyl group, so the order of priorities is

$$\mathrm{I} > \mathrm{C}\,(\text{bromoethyl}) > \mathrm{C}\,(\text{methyl}) > \mathrm{H}$$

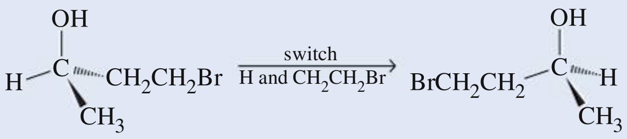
Viewing the molecule toward the lowest priority H atom is not quite as straightforward as in part (a). This is because the H atom is in the plane of the paper and thus not as far away from the viewers as possible. We can tackle this problem in one of two ways. The first requires some three-dimensional "vision," or "stereoperception," in that we imagine picking up the molecule by the methyl group and bromoethyl group and reorienting the molecule so that the H atom points away from us, to give



OH
H
C
CH$_2$CH$_2$Br
CH$_3$
OH
C
H$_3$C
CH$_2$CH$_2$Br

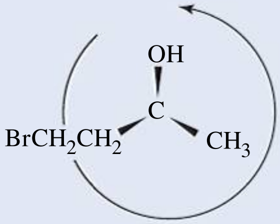
where we can now discern the sequence of priorities as clockwise, so the compound is (*R*)-4-bromo-2-butanol.

Alternatively, we can switch a pair of groups so that the group of lowest priority is bonded by a dashed wedge.



OH
H
C
CH$_2$CH$_2$Br
CH$_3$
switch
H and CH$_2$CH$_2$Br
OH
BrCH$_2$CH$_2$
C
H
CH$_3$

Now draw the view of the molecule toward the group of lowest priority. Here the sequence of priorities is counterclockwise. Because we switched two groups, we created the enantiomer of the molecule whose configuration we are actually seeking. Thus, although in the switched molecule the order of priorities corresponds to an *S* configuration, the *original* molecule corresponds to the *R* configuration. Therefore, as determined previously, the molecule is (*R*)-4-bromo-2-butanol.

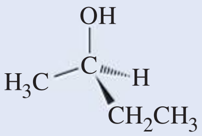


Assess

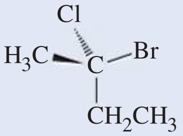
When assigning priorities to groups, it may be necessary, as it was in **(b)**, to work backward along the chain to find the first point of difference and then compare the atomic numbers of the atoms at that point.

PRACTICE EXAMPLE A: Indicate whether each of the following structures has the *R* configuration or the *S* configuration.

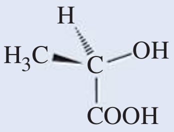
(a)



(b)

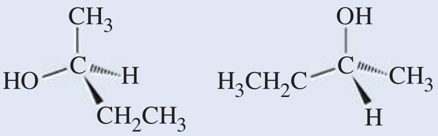


(c)

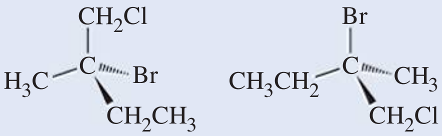


PRACTICE EXAMPLE B: Do the structures in each of the following pairs represent identical molecules or pairs of enantiomers?

(a)



(b)



26-5 Alkenes and Alkynes

A straight- or branched-chain alkane, with formula C_nH_{2n+2}, has the maximum number of H atoms possible for its number of C atoms. In other classes of hydrocarbons, compounds with the same number of C atoms but fewer H atoms, the C atoms must join into rings, form carbon-to-carbon multiple bonds, or do both to ensure that each C atom forms a total of four bonds. We have already discussed some aspects of ring structures (in Section 26-3). In this section, we focus on hydrocarbons whose molecules contain some double or triple bonds between C atoms. Such molecules are said to be **unsaturated**. If the molecule has *one double bond*, the hydrocarbons are the simple **alkenes**, or **olefins**; they have the general formula C_nH_{2n}. Simple alkynes have *one triple bond* in their molecules and have the general formula C_nH_{2n-2}.

In the examples that follow, systematic names are shown in blue. The names given in parentheses are also commonly used.

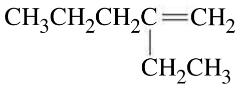
$CH_2{=}CH_2$

Ethene

(ethylene)

$CH_3CH_2CH{=}CH_2$

1-Butene



$$CH_3CH_2CH_2\underset{\displaystyle CH_2CH_3}{\underset{|}{C}}{=}CH_2$$

2-Ethyl-1-pentene

$HC{\equiv}CH$

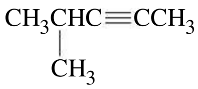
Ethyne

(acetylene)

$CH_3CH_2C{\equiv}CH$

1-Butyne

(ethylacetylene)



$$CH_3\underset{\displaystyle CH_3}{\underset{|}{C}}HC{\equiv}CCH_3$$

4-Methyl-2-pentyne

(isopropylmethylacetylene)

The following are the modifications of the rules on page 1151 required to name alkenes and alkynes:

1. Select as the base chain the longest chain containing the multiple bond.
2. Number the C atoms of the chain to place the multiple bond at the lowest possible number.
3. Use the ending *-ene* for alkenes and *-yne* for alkynes.

Thus, in the name 2-ethyl-1-pentene, the longest chain *containing the multiple bond* is a five-carbon chain (*pent-*). This is *not* a substituted hexane, and it is *not* a hexene. The double bond makes the molecule an alkene, and its location between the first and second carbon makes it a 1-pentene. The ethyl group is attached to the second C atom, and so the alkene is named 2-ethyl-1-pentene.

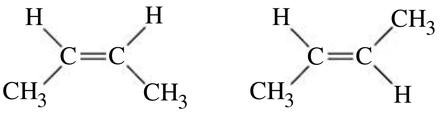
The alkenes are similar to the alkanes in physical properties. At room temperature, those containing 2 to 4 C atoms are gases; those with 5 to 18 are liquids; those with more than 18 are solids. In general, alkynes have higher boiling points than their alkane and alkene counterparts.

Stereoisomerism in Alkenes

The molecules 2-butene, $CH_3CH{=}CHCH_3$, and 1-butene, $CH_2{=}CHCH_2CH_3$, differ in the position of the double bond and are constitutional isomers. However, another type of isomerism is possible in 2-butene, as shown in the two structures below:

KEEP IN MIND

that *cis* means "on the same side" and *trans* means "across."

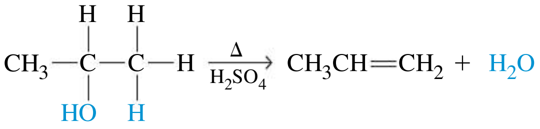


(a) *cis*-2-Butene (b) *trans*-2-Butene

The two isomers of 2-butene are stereoisomers because they have exactly the same *constitution* but a different spatial arrangement of their atoms in space. As we learned in Section 11-4, a double bond between C atoms consists of the overlap of hybrid orbitals to form a σ bond *and* the sideways overlap of *p* orbitals to form a π bond. Because of the π bond, rotation about a double bond is severely restricted. Molecule (a) cannot be converted into molecule (b) simply by twisting one end of the molecule through 180°, so the two molecules are distinctly different above. To differentiate these two molecules, we call molecule (a) *cis*-2-butene and we call molecule (b) *trans*-2-butene. Because of differences in their molecular structures, the compounds have different physical properties. For example, the melting points are −139 °C for *cis*-2-butene and −106 °C for *trans*-2-butene; the boiling points are 3.7 °C for *cis*-2-butene and 0.9 °C for *trans*-2-butene.

Preparation and Uses of Alkenes and Alkynes

The general laboratory preparation of alkenes uses an *elimination reaction*, a reaction in which atoms are removed from adjacent positions on a carbon chain. Elimination reactions will be examined in more detail in Chapter 27. For now, it is enough to know that, in an elimination reaction, a small molecule is produced, and an additional bond is formed between the C atoms. For example, H_2O is eliminated in the following reaction:



$$CH_3-\underset{HO}{\overset{H}{C}}-\underset{H}{\overset{H}{C}}-H \xrightarrow[H_2SO_4]{\Delta} CH_3CH{=}CH_2 + H_2O \qquad (26.4)$$

The principal alkene of the chemical industry is ethene (ethylene). Its chief use is in the manufacture of polymers (Chapter 27), although it is also used to manufacture other organic chemicals. Reaction (26.4) is relatively unimportant in the commercial production of ethylene, which is obtained mainly by thermal cracking of other hydrocarbons.

The simplest alkyne is ethyne (acetylene), which can be prepared from coal, water, and limestone in a three-step process:

$$CaCO_3 \xrightarrow{\Delta} CaO + CO_2$$

$$CaO + 3\,C \xrightarrow[2000\ ^\circ\mathrm{C}]{\text{electric furnace}} \underset{\substack{\text{calcium acetylide}\\ \text{(calcium carbide)}}}{CaC_2} + CO$$

$$CaC_2 + 2\,H_2O \longrightarrow \underset{\text{acetylene}}{HC{\equiv}CH} + Ca(OH)_2 \tag{26.5}$$

Most other alkynes are prepared from acetylene by taking advantage of the acidity of the C—H bond. In the presence of a very strong base, such as sodium amide ($NaNH_2$), the amide anion removes the proton from acetylene to form ammonia and the salt sodium acetylide. The acetylide can then react with an alkyl halide, such as CH_3Br:

$$H{-}C{\equiv}C{-}H + Na^+NH_2^- \longrightarrow H{-}C{\equiv}C^-Na^+ + NH_3$$

$$H{-}C{\equiv}C^-Na^+ + CH_3Br \longrightarrow H{-}C{\equiv}C{-}CH_3 + Na^+Br^- \tag{26.6}$$

By continuing this reaction, the triple bond can be positioned as desired in the chain, as in the synthesis of 2-pentyne:

$$H{-}C{\equiv}C{-}CH_3 + NaNH_2 \longrightarrow Na^{+\,-}C{\equiv}C{-}CH_3 + NH_3$$

$$Na^{+\,-}C{\equiv}C{-}CH_3 + CH_3CH_2Br \longrightarrow CH_3CH_2C{\equiv}CCH_3 + Na^+Br^- \tag{26.7}$$

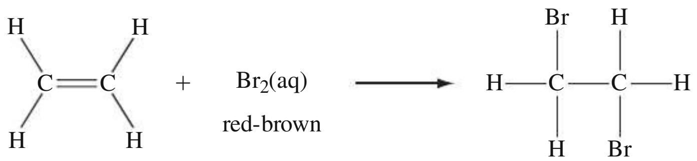
At one time, acetylene was one of the most important organic raw materials in the chemical industry. At present, the chief use of acetylene is in the manufacture of other chemicals for polymer production, such as vinyl chloride, $H_2C{=}CHCl$, which is polymerized to polyvinyl chloride (PVC). We will discuss polymers and polymerization reactions in the next chapter.

Acetylene is also used to produce high-temperature flames that are used in a variety of applications. For example, the combustion of acetylene in excess oxygen is the basis of oxyacetylene torches used for cutting and welding metals.

$$HC{\equiv}CH(g) + \frac{5}{2}\,O_2(g) \longrightarrow 2\,CO_2(g) + H_2O(l) \qquad \Delta H = -1300\ \mathrm{kJ}$$

The large negative enthalpy of combustion of acetylene results from acetylene's large *positive* enthalpy of formation: $\Delta H_f^\circ[C_2H_2(g)] = +226.7\ \mathrm{kJ\ mol^{-1}}$.

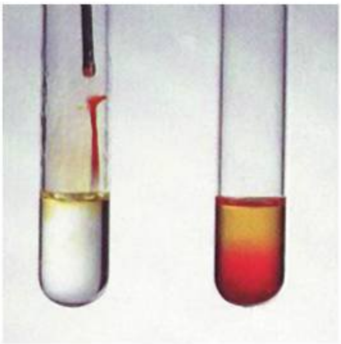
Alkenes and alkynes are used by chemists to make other compounds. The reactive part of these compounds are the π bonds and the characteristic reaction is an addition reaction, in which atoms or grouping of atoms add to the carbon atoms on either side of a double or triple bond. We have already seen one example of an addition reaction, reaction (26.1), in which hydrogen atoms add across a carbon–carbon bond of an alkene to give an alkane. Although we will examine reactions of alkenes in more detail in Chapter 27, it is worth mentioning now that certain addition reactions form the basis of simple qualitative tests that can be used to determine whether a compound is an alkene or an alkyne. For example, $H_2C{=}CH_2$ will absorb H_2 in the presence of a metal catalyst, reaction (26.1), and it will decolorize a solution of bromine water, $Br_2(aq)$, because of the following reaction:



(26.8)

The decolorization of bromine by cyclohexene can be seen in the photo in the margin on the next page.

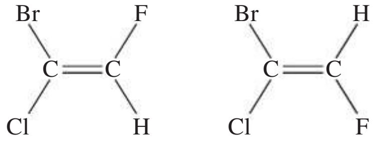
▲ Cutting steel with an oxyacetylene torch.



▲ The test tube on the left contains cyclohexene and the one on the right contains cyclohexane. When bromine Br_2, is added to the tube containing cyclohexene, the red-brown color disappears because Br_2 adds across the double bond. The red-brown color persists in the tube filled with cyclohexane.

Naming the Stereoisomers of Highly Substituted Alkenes: The *E*, *Z* System of Nomenclature

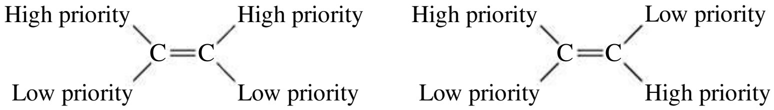
Unfortunately, the *cis–trans* nomenclature is not useful for naming highly substituted alkenes. Consider for example the following stereoisomers of 1-bromo-1-chloro-2-fluoroethene:



Br
F
C=C
Cl
H
Br
H
C=C
Cl
F

Which is *cis*? Which is *trans*?

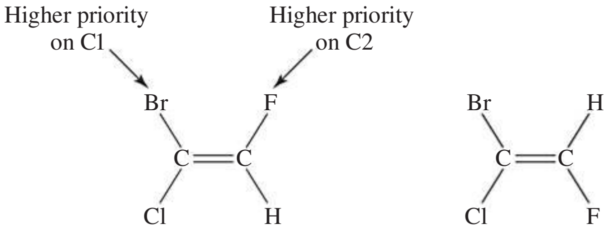
In the structure on the left, the F atom is *cis* to Br and *trans* to Cl; in the structure on the right, F is *cis* to Cl and *trans* to Br. Clearly, the *cis–trans* descriptors are not very helpful for naming highly substituted alkenes. An alternative system for naming such alkenes has been adopted by IUPAC: the ***E*, *Z* system**. The Cahn–Ingold–Prelog rules, discussed previously, are used systematically to assign priorities to the substituents on the carbon atoms of the double bond. The stereochemistry about the double bond is assigned *Z* (from the German word *zusammen*, meaning "together") if the two groups of higher priority *at each end of the double bond* are on the same side of the molecule. If the two groups of higher priority are on opposite sides of the double bond, the configuration is denoted by an *E* (from the German word *entgegen*, meaning "opposite"). These ideas are summarized in the diagram below:



High priority
High priority
C=C
Low priority
Low priority
High priority
Low priority
C=C
Low priority
High priority

The *Z* isomer The *E* isomer

We can use the *E*, *Z* system to name the two stereoisomers of 1-bromo-1-chloro-2-fluoroethene:



Higher priority on C1
Higher priority on C2
Br
F
C=C
Cl
H
Br
H
C=C
Cl
F

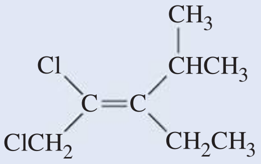
(*Z*)-1-bromo-1-chloro-2-fluoroethene (*E*)-1-bromo-1-chloro-2-fluoroethene

Note that, as in *R*, *S* nomenclature, the *E* or *Z* is placed in parentheses. The *E*, *Z* system of nomenclature can be used for all alkene stereoisomers; consequently, the IUPAC recommends that this system be used exclusively. However, many chemists continue to use the *cis* and *trans* designations for simple alkenes.

EXAMPLE 26-9 Assignment of Configurations of Alkenes

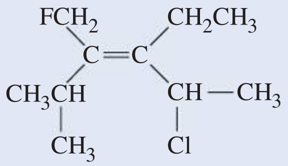
Name each of the following compounds, including the assignment of configuration.

(a)



CH_3
Cl
$CHCH_3$
C=C
$ClCH_2$
CH_2CH_3

(b)



FCH_2
CH_2CH_3
C=C
CH_3CH
$CH-CH_3$
CH_3
Cl

Analyze

To assign the configuration of the alkene, we must first assign the priorities to the substituents attached to each carbon in the double bond. Once this is done, we can assign the *E* or *Z* designation.

Solve

(a) One of the sp^2 carbon atoms is bonded to a Cl atom and a C atom; thus, the chlorine atom has highest priority. The other sp^2 carbon is bonded to an ethyl group and an isopropyl group. The carbon of the isopropyl group is bonded to C, C, and H, and the carbon of the ethyl group to C, H, and H. A carbon can be canceled in each group. Of the remaining atoms, the carbon has the highest priority. Thus, the isopropyl group takes precedence. The groups of highest priority are on the same side of the double bond. The complete name of the molecule is (*Z*)-1,2-dichloro-3-ethyl-4-methyl-2-pentene.

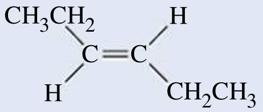
(b) One of the sp^2 carbon atoms is bonded to a fluoromethyl group and an isopropyl group. The carbon of the fluoromethyl group is bonded to F, H, and H; the carbon of the isopropyl group to C, C, and H. Of these six atoms, the fluorine has the highest priority. Thus, the fluoromethyl group takes precedence. The other sp^2 carbon atom is bonded to an ethyl group and a chloroethyl group. Because the first point of difference on these substituent chains is a Cl atom, the chloroethyl group takes precedence. The groups of highest priority are on opposite sides of the double bond. The complete name of the molecule is (*E*)-2-chloro-3-ethyl-4-fluoromethyl-5-methyl-3-hexene.

Assess

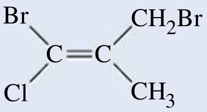
For **(b)**, the carbon atom bonded to chlorine is chiral and so, the molecule exists as either the *R* or *S* enantiomer. It takes quite a bit of practice to master organic nomenclature and, admittedly, it is not the most exciting of topics. However, it is an important part of organic chemistry. There could very well be someone else who shares your name, but there is only one (*Z*)-1,2-dichloro-3-ethyl-4-methyl-2-pentene!

PRACTICE EXAMPLE A: Assign a configuration to each of the following alkenes:

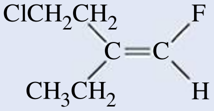
(a)



(b)



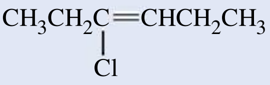
(c)



PRACTICE EXAMPLE B: Draw and label the *E* and *Z* isomers of the following compounds:

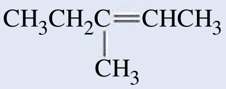
(a) $CH_3CH_2CH{=}CHCH_3$

(b)



$CH_3CH_2\underset{\displaystyle Cl}{C}{=}CHCH_2CH_3$

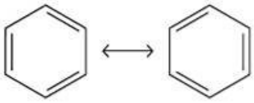
(c)



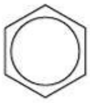
$CH_3CH_2\underset{\displaystyle CH_3}{C}{=}CHCH_3$

26-6 Aromatic Hydrocarbons

Aromatic hydrocarbons have ring structures with unsaturation (multiple-bond character) in the carbon-to-carbon bonds in the rings. Most aromatic hydrocarbons are based on the molecule benzene, C_6H_6. In Section 11-6, bonding in the benzene molecule was discussed in some detail. Several ways of representing the molecule were shown, including those in the margin.



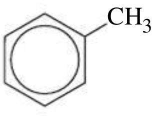
Kekulé structures



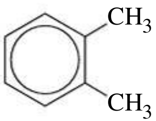
Simplified molecular orbital representation

▲ As in the case of alicyclic compounds, neither the C atoms at the vertices nor the H atoms bonded to them are shown in these structures.

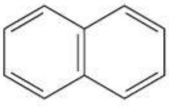
Other examples of aromatic hydrocarbons include



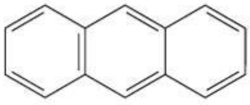
Toluene



o-Xylene



Naphthalene



Anthracene

Toluene and *o*-xylene are *substituted benzenes*, and naphthalene and anthracene feature *fused benzene rings*. When rings are fused together, the resultant structure has two C and four H atoms fewer than the starting structures. Thus, the formula for naphthalene is $C_6H_6 + C_6H_6 - 2\,C - 4\,H = C_{10}H_8$; for anthracene: $C_{10}H_8 + C_6H_6 - 2\,C - 4\,H = C_{14}H_{10}$. In this text, we use the inscribed circle for the simple benzene ring and alternating single and double bonds for fused rings. For the fused-ring systems, the bond arrangement represents one of the possible resonance structures for the molecule.

A. KEKULE
BENZEEN
BENZENE
BELGIE-BELGIQUE

▲ August Kekulé (1829–1896), who proposed the hexagonal ring structure for benzene in 1865. His representation of this molecule is still widely used.

Characteristics of Aromatic Hydrocarbons

Aromatic hydrocarbons are highly flammable and should always be handled with care. Prolonged inhalation of benzene vapor results in a decreased production of both red blood cells and white blood cells, which can be fatal. Also, benzene is a carcinogen. Benzene and some other toxic aromatic compounds have been isolated in the tar formed by burning cigarettes, in polluted air, and as a decomposition product of grease in the charcoal grilling of meat.

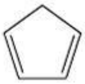
A close examination of the structures of aromatic molecules shows that they all share two common features.

- They are *planar* (flat), *cyclic* molecules.
- They have a *conjugated* bonding system—a bonding scheme among the ring atoms that consists of alternating single and double bonds. The system must extend throughout the ring, and the π electron clouds associated with the double bonds must involve $(4n + 2)$ electrons, where $n = 1, 2, \ldots$.

Thus, the benzene molecule has six electrons in the π electron clouds: $(4 \times 1) + 2 = 6$. The naphthalene molecule has 10: $(4 \times 2) + 2 = 10$. And the anthracene molecule has 14: $(4 \times 3) + 2 = 14$.

$CH_2{=}CH{-}CH{=}CH{-}CH{=}CH_2$

1,3,5-Hexatriene

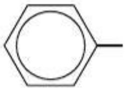


1,3-Cyclopentadiene

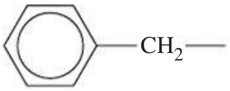
Neither of the two molecules depicted in the margin is aromatic. The 1,3,5-hexatriene molecule has six π electrons in its conjugated bonding system, but it is not cyclic. The 1,3-cyclopentadiene molecule is cyclic, but has only four π electrons in a conjugated bonding system that does not extend completely around the ring.

Benzene and its homologues are similar to other hydrocarbons in being insoluble in water but soluble in organic solvents. The boiling points of the aromatic hydrocarbons are slightly higher than those of the alkanes of similar carbon content. For example, hexane, C_6H_{14}, boils at 69 °C, whereas benzene boils at 80 °C. This can be explained by the planar structure and delocalized electron charge density of benzene, which increases the attractive forces between molecules. The symmetrical structure of benzene permits closer packing of molecules in the crystalline state and results in a higher melting point than for hexane. Benzene melts at 5.5 °C and hexane melts at −95 °C.

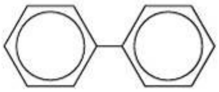
Two important aromatic functional groups are the phenyl and benzyl groups. A **phenyl group** is obtained when one of the six equivalent H atoms of a benzene molecule is removed. A **benzyl group** is obtained by replacing one of the H atoms in a methyl group with a phenyl group.



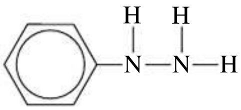
Phenyl group



Benzyl group



Biphenyl



Phenylhydrazine

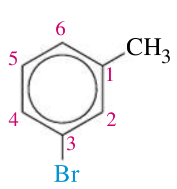
Two phenyl groups may bond together, as in biphenyl, or phenyl groups may be substituents in other molecules, as in phenylhydrazine, used in the detection of sugars. The structures of biphenyl and phenylhydrazine are shown in the margin.

26-10 CONCEPT ASSESSMENT

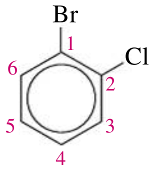
What is the structure of the molecule with the name (*E*)-3-benzyl-2,5-dichloro-4-methyl-3-hexene?

Naming Aromatic Hydrocarbons

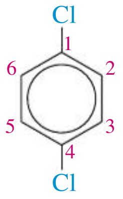
Other atoms or groups may be substituted for H atoms on the benzene molecule, and to name these compounds, we use a numbering system for the C atoms in the ring. If the name of an aromatic compound is based on a common name other than benzene (such as toluene), the characteristic substituent group (for example, the —CH_3 in toluene) is assigned position "1" on the benzene ring. Otherwise, the substituents are listed alphabetically and the carbon atoms in the ring are numbered so that the substituents appear at the lowest numbers possible, as shown below for 1-bromo-2-chlorobenzene.



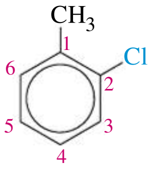
3-Bromotoluene
(*m*-bromotoluene)



1-bromo-2-chlorobenzene
(*o*-bromochlorobenzene)



1,4-Dichlorobenzene
(*p*-dichlorobenzene)



2-Chlorotoluene
(*o*-chlorotoluene)

The terms *ortho, meta,* and *para* (*o*-, *m*-, *p*-) can be used when there are two substituents on the benzene ring. **Ortho** refers to substituents on adjacent carbon atoms, **meta** to substituents with one carbon atom between them, and **para** to substituents opposite one another on the ring.

◀ *p*-dichlorobenzene is used in mothballs. Naphthalene has also been used in mothballs but is being replaced by *p*-dichlorobenzene because *p*-dichlorobenzene has a less intense smell.

Uses of Aromatic Hydrocarbons

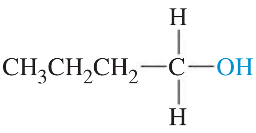
Over 90% of the billions of pounds of benzene produced annually in the United States is derived from petroleum. The process involves dehydrogenation and cyclization of hexane to the aromatic hydrocarbon. The most important use of the petroleum-produced benzene is in manufacturing ethylbenzene for the production of styrene plastics. Other applications include the manufacture of phenol, the synthesis of dodecylbenzene (for detergents), and as an octane enhancer in gasoline. The production of aromatic compounds by dehydrogenation (removal of hydrogen) of alkanes yields large amounts of hydrogen gas, which is an important reactant in the synthesis of ammonia (page 1008).

26-7 Organic Compounds Containing Functional Groups

In this section we will describe the structure and nomenclature of organic compounds containing functional groups. We will defer a discussion of the chemical transformations between some of them until the next chapter. As we proceed you will see how all the stereochemistry that we have discussed is also applied to these molecules.

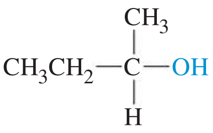
Alcohols and Phenols

Alcohols and **phenols** are characterized by the **hydroxyl** group, —OH. In alcohols, the hydroxyl group is bound to an sp^3 hybridized (aliphatic) carbon atom. If this C atom also has *one* R group (and two H atoms) bonded to it, the alcohol is a *primary* alcohol. If the C atom has *two* R groups (and one H atom), the alcohol is a *secondary* alcohol. Finally, if there are *three* R groups on the C atom (and no H atoms), the alcohol is a *tertiary* alcohol. The systematic naming of alcohols uses the suffix *-ol* and was discussed in Chapter 3. In phenols, the hydroxyl group is attached to a benzene ring.



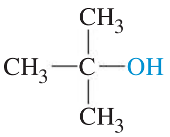
$$CH_3CH_2CH_2-\overset{\displaystyle H}{\underset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}-OH$$

1-Butanol
(butyl alcohol)
(a *primary* alcohol)



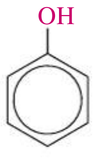
$$CH_3CH_2-\overset{\displaystyle CH_3}{\underset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}-OH$$

2-Butanol
(*sec*-butyl alcohol)
(a *secondary* alcohol)

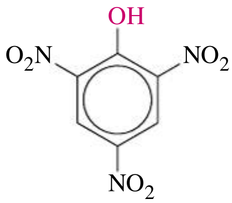


$$CH_3-\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{\overset{|}{\underset{|}{C}}}}-OH$$

Methyl-2-propanol
(*tert*-butyl alcohol)
(a *tertiary* alcohol)

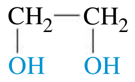


Phenol
(carbolic acid)



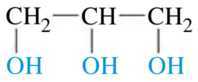
2,4,6-Trinitrophenol
(picric acid)

A molecule may have more than one —OH group. Those with two —OH groups are known as *diols* (or glycols), and those with more than two —OH groups are called *polyols*. Ethylene glycol, a diol, is used in automobile antifreeze solutions; glycerol, a polyol, is an important biological molecule used as part of the body's mechanism for fat storage.



$$\underset{\text{OH}}{\overset{}{CH_2}}-\underset{\text{OH}}{\overset{}{CH_2}}$$

1,2-Ethanediol
(ethylene glycol)



$$\underset{\text{OH}}{CH_2}-\underset{\text{OH}}{CH}-\underset{\text{OH}}{CH_2}$$

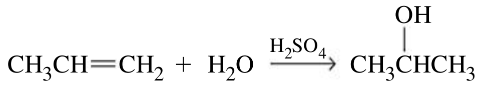
1,2,3-Propanetriol
(glycerol)

Physical properties of aliphatic alcohols are strongly influenced by hydrogen bonding. As the chain length increases, however, the influence of the polar hydroxyl group on the properties of the molecule diminishes. The molecule becomes less like water and more like a hydrocarbon. As a consequence, low-molecular mass alcohols tend to be water soluble, whereas high-molecular mass alcohols are not. The boiling points and solubilities of the phenols vary widely, depending on the nature of the other substituents on the benzene ring.

26-11 CONCEPT ASSESSMENT

Explain why the name *sec*-pentyl alcohol does not unambiguously identify a compound whereas the name *sec*-butyl alcohol does.

Preparation and Uses of Alcohols Two methods by which alcohols can be synthesized are by the hydration of alkenes and the hydrolysis of alkyl halides.



$$CH_3CH{=}CH_2 + H_2O \xrightarrow{H_2SO_4} CH_3\overset{\overset{\text{OH}}{|}}{C}HCH_3 \qquad (26.9)$$

propene (propylene) — 2-propanol (isopropyl alcohol)

$$CH_3CH_2CH_2Br + OH^- \longrightarrow CH_3CH_2CH_2OH + Br^- \qquad (26.10)$$

1-bromopropane — 1-propanol

Reaction (26.9) is an example of an *addition reaction* and reaction (26.10) is an example of a *substitution reaction*. In an addition reaction, one or more atoms add to a molecule. In a substitution reaction, an atom or a grouping of atoms is replaced by another atom or group of atoms. We will have a closer look at these types of reactions in Chapter 27.

Methanol (wood alcohol) is the simplest alcohol. It is a highly toxic substance that can lead to blindness or death if ingested. Most methanol is manufactured from carbon monoxide and hydrogen.

$$CO(g) + 2\,H_2(g) \xrightarrow[200\text{ atm}]{350\text{ °C}} CH_3OH(g)$$
$$ZnO,\ Cr_2O_3$$

Methanol is the most extensively produced alcohol. It is used in the synthesis of other organic chemicals and as a solvent, but potentially its most important use may be as a motor fuel (recall Section 7-9).

Ethanol, CH_3CH_2OH, is grain alcohol, which is found in alcoholic beverages. It is easily produced by the fermentation of the juices of sugarcane or other materials that contain natural sugars. The industrial method involves the hydration of ethylene with sulfuric acid catalyst (similar to reaction 26.9).

Ethylene glycol, $HOCH_2CH_2OH$, is water soluble and has a higher boiling point (197 °C) than water. These properties make it an excellent permanent, nonvolatile antifreeze for automobile radiators. It is also used in the manufacture of solvents, paint removers, and plasticizers (softeners).

Glycerol (glycerin), $HOCH_2CH(OH)CH_2OH$, is obtained commercially as a by-product in the manufacture of soap. It is a sweet, syrupy liquid that is miscible with water in all proportions. Because it takes up moisture from the air, glycerol can be used to keep skin moist and soft and is found in lotions and cosmetics.

An interesting and useful derivative of an alcohol is the alkoxide ion, RO^-, a deprotonated form of the alcohol. The alkoxide ion is formed by the reaction of sodium or potassium metal with the alcohol. For example, the methoxide ion, CH_3O^-, is produced in the following reaction:

$$CH_3OH + Na \longrightarrow CH_3O^- + Na^+ + \frac{1}{2}H_2(g) \qquad \textbf{(26.11)}$$

Reaction (26.11) provides the basis of a simple qualitative test that is sometimes used to confirm whether a compound is an alcohol. For alcohols, the addition of sodium metal results in the formation of $H_2(g)$ bubbles. Reaction (26.11) is more commonly used to produce alkoxide ions that can be used in other reactions. For example, an alkoxide ion can react with a haloalkane, as suggested below:

$$CH_3O^- + CH_3CH_2Cl \longrightarrow CH_3OCH_2CH_3 + Cl^-$$

This reaction is yet another example of a substitution reaction (Chapter 27). The compound formed is an ether, discussed next.

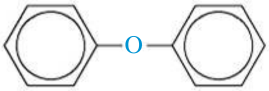
▲ **Giant soap bubble**
A soap bubble consists of an air pocket enclosed in a thin film of soap in water. As the water evaporates, the film breaks and the bubble bursts. Glycerol added to the soap–water mixture forms hydrogen bonds to both the soap and water molecules. This slows the rate of evaporation of the water and increases the strength of the film, allowing the production of very large bubbles.

Ethers

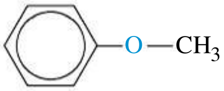
An **ether** is a compound with the general formula R—O—R′. Structurally, ethers can be pure aliphatic, pure aromatic, or mixed.

$CH_3—O—CH_3$

Dimethyl ether



Diphenyl ether

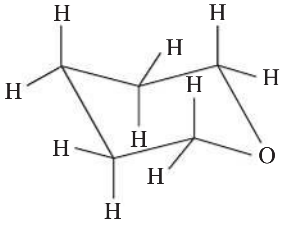


Methyl phenyl ether
(anisole)

Dimethyl ether has the same formula as ethanol, but the two substances have quite different physical and chemical properties. They have different properties because each has a different functional group (see Table 26.2). Dimethyl ether and ethanol are constitutional isomers.

Ethers can be viewed as alkane or aromatic compounds containing the group RO—; this group is known as the *alkoxy group*. The IUPAC system for naming ethers treats them as alkanes that bear an alkoxy substituent, that is, as alkoxyalkanes. The smaller substituent is considered part of the alkoxy group and the larger substituent defines the stem. Thus, for example, the IUPAC name for ethylmethyl ether is methoxyethane, and for anisole, it is methoxybenzene.

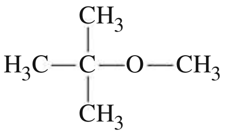
Ethers can also be cyclic. For example, if an oxygen atom takes the place of a carbon atom in a cyclohexane molecule, we obtain the cyclic ether shown in the margin. The oxygen atom in this structure is called a *heteroatom* (because it is not a carbon atom) and the compound is called a **heterocyclic compound**. The simplest system for naming cyclic ethers is based on using the prefix *oxa-* in front of the name of the cycloalkane. The prefix *oxa-* indicates that a carbon atom has been replaced by an oxygen atom. Thus, the name of the compound above is oxacyclohexane.



Preparation and Uses of Ethers Symmetrical ethers, such as diethyl ether, can be prepared by the elimination of a water molecule from between two alcohol molecules with a strong dehydrating agent, such as concentrated H_2SO_4.

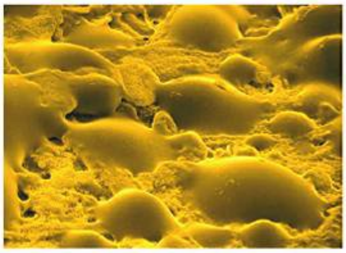
$$CH_3CH_2OH + HOCH_2CH_3 \xrightarrow[140\ ^\circ C]{\text{conc. } H_2SO_4} CH_3CH_2OCH_2CH_3 + H_2O \qquad \textbf{(26.12)}$$

▶ The molecule below should be named *tert*-butyl methyl ether (TBME), but has been referred to by industrial chemists as MTBE for so long that methyl *tert*-butyl ether has become the commonly used name for this compound.

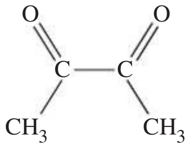


$$H_3C-\overset{CH_3}{\underset{CH_3}{C}}-O-CH_3$$

Methyl *tert*-butyl ether (MTBE)



▲ False-color scanning electron micrograph of the sticky surface of a 3M Post-it note. The bubbles are 15–40 μm in diameter and consist of a urea–formaldehyde adhesive. Each time the note is pressed to a surface, fresh adhesive is released. The note can be reattached to a surface as long as some of the bubbles remain.



Butanedione, a diketone

KEEP IN MIND

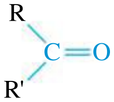
that the CHO functional group can be only at the terminus of a carbon chain, whereas the CO functional group cannot be at the end of a carbon chain.

Chemically, ethers are comparatively unreactive. The ether linkage is stable in the presence of most oxidizing and reducing agents, as well as dilute acids and alkalis.

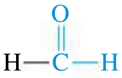
Diethyl ether has been used extensively as a general anesthetic. It is easy to administer and produces excellent relaxation of the muscles. Also, it affects the pulse rate, rate of respiration, and blood pressure only slightly. However, it is somewhat irritating to the respiratory passages and produces nausea. Methyl propyl ether (neothyl) is also used as an anesthetic and is less irritating to the respiratory passages. Dimethyl ether, a gas at room temperatures, is used as a propellant for aerosol sprays. Higher molecular mass ethers are used as solvents for varnishes and lacquers. Methyl *tert*-butyl ether, an unsymmetrical ether, marketed under the name MTBE, has been used as an octane enhancer in gasoline. However, because of its relatively high solubility in water ($\approx$5 g/100 g H_2O), in some localities it has caused rather extensive groundwater pollution through leakage from underground storage tanks; it is currently being phased out of use.

Aldehydes and Ketones

Aldehydes and ketones contain the **carbonyl group**.

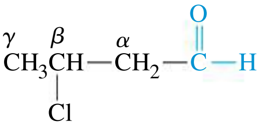


If either the R or R′ group is an H atom, the compound is an **aldehyde**. If the R and R′ groups are alkyl or aromatic (aryl) groups, the compound is a **ketone**.



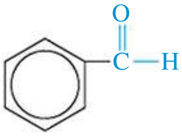
$$H-\overset{\overset{O}{\|}}{C}-H$$

Methanal
(formaldehyde)

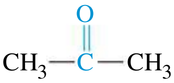


$$\overset{\gamma}{C}H_3\overset{\beta}{C}H(Cl)-\overset{\alpha}{C}H_2-\overset{\overset{O}{\|}}{C}-H$$

3-Chlorobutanal
(β-chlorobutyraldehyde)

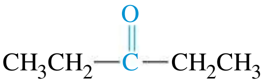


Benzaldehyde



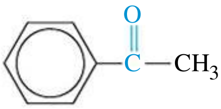
$$CH_3-\overset{\overset{O}{\|}}{C}-CH_3$$

Propanone
(acetone)



$$CH_3CH_2-\overset{\overset{O}{\|}}{C}-CH_2CH_3$$

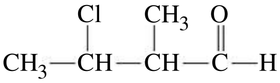
3-Pentanone
(diethyl ketone)



1-Phenylethanone
(acetophenone)

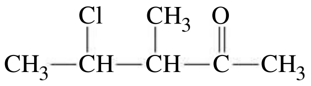
Aldehydes and ketones often have characteristic and recognizable odors. For example, 2-heptanone is a liquid with a clove-like odor that accounts for the odors of many fruits and dairy products. Some aldehydes and ketones find use as flavoring agents. For example, vanillin, the compound responsible for vanilla flavor, is an aldehyde. Alpha-demascone and 2-octanone are ketones responsible for berry and mushroom flavors, respectively. Butanedione, shown in the margin, is a yellow liquid with a cheese-like smell that gives butter its flavor.

The IUPAC naming system for aldehydes uses the suffix *-al*. The parent chain is the longest chain containing the aldehyde group. Accordingly, the four-carbon aldehyde is called butanal because the name is derived from the alkane (butane) with the *-e* replaced by *-al*. The numbering of the chain starts at the carbon of the aldehyde group; it is always at position one and need not be specified. Thus 3-chloro-2-methylbutanal is



$$CH_3-\overset{Cl}{\overset{|}{C}H}-\overset{CH_3}{\overset{|}{C}H}-\overset{\overset{O}{\|}}{C}-H$$

The IUPAC naming system for ketones uses the suffix *-one*. The parent chain must include the carbonyl group and be numbered from the end of the chain that reaches the carbonyl group first; this ensures, as required by IUPAC rules, that the number for the carbonyl group is as low as possible. For example, the molecule



$$\mathrm{CH_3{-}\overset{\overset{\large Cl}{|}}{C}H{-}\overset{\overset{\large CH_3}{|}}{C}H{-}\overset{\overset{\large O}{\|}}{C}{-}CH_3}$$

is 4-chloro-3-methyl-2-pentanone.

Preparation and Uses of Aldehydes and Ketones Aldehydes can be produced by the oxidation of a *primary* alcohol with an oxidizing agent such as dichromate ion in acidic solution. However, the aldehyde so formed is readily oxidized further to a carboxylic acid.

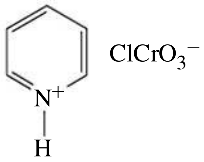
$$\mathrm{CH_3CH_2OH} \xrightarrow[\mathrm{H^+}]{\mathrm{Cr_2O_7{}^{2-}}} \mathrm{CH_3CHO} \xrightarrow[\mathrm{H^+}]{\mathrm{Cr_2O_7{}^{2-}}} \mathrm{CH_3CO_2H} \qquad \mathbf{(26.13)}$$

ethanol (a primary alcohol) — acetaldehyde (an aldehyde) — acetic acid (an acid)

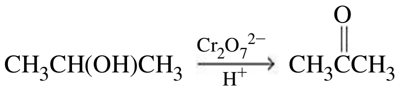
A milder oxidizing agent in a nonaqueous medium is required to stop the oxidation at the aldehyde. This partial oxidation can be done with the reagent pyridinium chlorochromate (PCC) in an organic solvent such as dichloromethane. For example,

$$\mathrm{CH_3(CH_2)_8CH_2OH} \xrightarrow{\mathrm{PCC,\ CH_2Cl_2}} \mathrm{CH_3(CH_2)_8CHO}$$

◀ PCC is formed as yellow-orange crystals by the reaction between CrO_3 and HCl in pyridine.



Oxidation of a *secondary* alcohol produces a ketone.



$$\mathrm{CH_3CH(OH)CH_3} \xrightarrow[\mathrm{H^+}]{\mathrm{Cr_2O_7{}^{2-}}} \mathrm{CH_3\overset{\overset{\large O}{\|}}{C}CH_3} \qquad \mathbf{(26.14)}$$

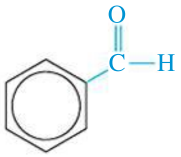
2-propanol (a secondary alcohol) — acetone (a ketone)

Ketones are much more resistant to oxidation than are alcohols and aldehydes.

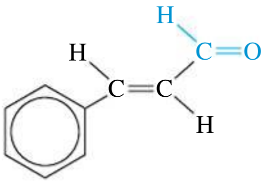
KEEP IN MIND

that tertiary alcohols cannot be oxidized to aldehydes or ketones because a tertiary carbon is bonded to three alkyl groups and cannot form a double bond with an oxygen atom unless one of the carbon–carbon bonds is broken. Oxidation of a tertiary alcohol is typically difficult and requires a very strong oxidizing agent.

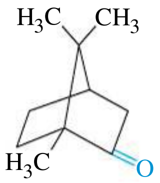
Aldehydes and ketones occur widely in nature. Typical natural sources are



Benzaldehyde
(almonds)

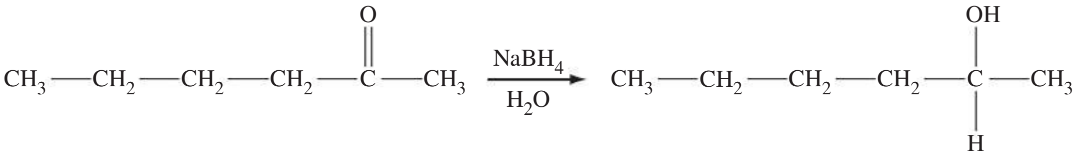


Cinnamaldehyde
(cinnamon)



Camphor
(obtained from
camphor tree)

Aldehydes and ketones can be reduced to primary and secondary alcohols, respectively, by sodium borohydride, $NaBH_4$. For example, 2-hexanone is reduced to 2-hexanol by $NaBH_4$:



$$\mathrm{CH_3{-}CH_2{-}CH_2{-}CH_2{-}\overset{\overset{\large O}{\|}}{C}{-}CH_3} \xrightarrow[\mathrm{H_2O}]{\mathrm{NaBH_4}} \mathrm{CH_3{-}CH_2{-}CH_2{-}CH_2{-}\underset{\underset{\large H}{|}}{\overset{\overset{\large OH}{|}}{C}}{-}CH_3}$$

The reaction effectively adds two H atoms across the carbon–oxygen double bond. However, H atoms are not directly involved. The reaction involves two distinct steps (1) attack of the carbonyl carbon atom by a hydride (H^-) ion; (2) protonation of the carbonyl oxygen atom.

Aldehydes and ketones find use as starting materials and reagents for the synthesis of other organic compounds, and, generally speaking, aldehydes are more reactive than ketones. The carbon atom in the carbonyl group is slightly positive and is prone to attack by species that are attracted to centers of positive charge.

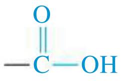
The simplest aldehyde is formaldehyde ($H_2C{=}O$), a colorless gas that dissolves readily in water. Billions of kilograms of formaldehyde are used each year in the manufacture of synthetic resins. A polymer of formaldehyde called paraformaldehyde is used as an antiseptic and an insecticide.

Acetone is the most important of the ketones. It is a volatile liquid (boiling point, 56 °C) and highly flammable. Acetone is a good solvent for a variety of organic compounds and is widely used in solvents for varnishes, lacquers, and plastics. Unlike many common organic solvents, acetone is miscible with water in all proportions.

Carboxylic Acids

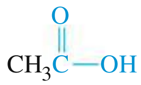
As we learned in Chapter 3, **carboxylic acids** contain the **carboxyl group** (*car*bonyl and hydr*oxyl*).

▶ The carboxyl group is represented either as —COOH or $-CO_2H$.



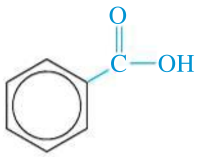
$$-\overset{O}{\overset{\|}{C}}-OH$$

These acids have the general formula R—COOH. In many compounds, R is an aliphatic residue. Such compounds are called fatty acids because high-molecular mass compounds of this type are readily available from naturally occurring fats and oils. If two carboxyl groups are found on the same molecule, the acid is called a dicarboxylic acid. The carboxyl group can also be found attached to the benzene ring.

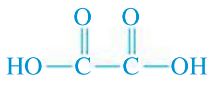


$$CH_3\overset{O}{\overset{\|}{C}}-OH$$

Acetic acid
(an aliphatic acid)

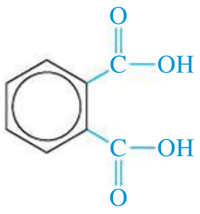


Benzoic acid
(an aromatic acid)



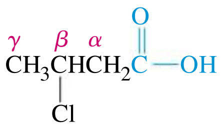
$$HO-\overset{O}{\overset{\|}{C}}-\overset{O}{\overset{\|}{C}}-OH$$

Oxalic acid
(an aliphatic
dicarboxylic acid)



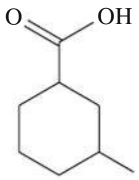
Phthalic acid
(an aromatic
dicarboxylic acid)

Straight- or branched-chain acids can be named either by their IUPAC names or by using Greek letters in conjunction with common names. Cycloalkanes with a —COOH substituent are named as *cycloalkanecarboxylic acids*; that is, the ending "carboxylic acid" is combined with the name of the cycloalkane. Aromatic acids are named as derivatives of benzoic acid. Here are a few examples:

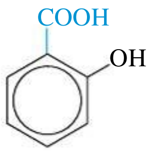


$$\overset{\gamma}{CH_3}\underset{\underset{Cl}{|}}{\overset{\beta}{C}}H\overset{\alpha}{CH_2}\overset{O}{\overset{\|}{C}}-OH$$

3-Chlorobutanoic acid
β-chlorobutyric acid



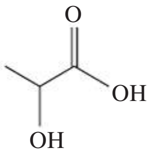
3-methylcyclohexanecarboxylic acid



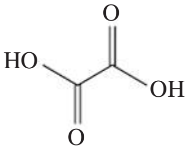
2-Hydroxybenzoic acid
o-hydroxybenzoic acid
(also salicylic acid)

Notice that in straight- or branched-chain carboxylic acids, the C atom in the —COOH group is C1, but in cyclic and aromatic acids, the C atom bonded to the —COOH group is C1.

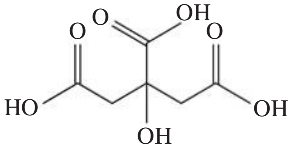
Carboxylic acids are found widely in nature. Spinach, rhubarb, and other green leafy vegetables are rich in *oxalic acid* (see previous page). Sour milk and sore muscles have elevated levels of *lactic acid*. Citrus fruits are rich in *citric acid*. Line-angle formulas for these acids are shown in the margin.



Lactic acid



Oxalic acid



Citric acid

Carboxylic acids, especially those of low molecular weight, exhibit characteristic odors. Ethanoic acid (acetic acid) is the acid that gives vinegar its characteristic smell. The presence of butanoic acid contributes to the strong flavor and aroma of many cheeses, and (*E*)-3-methyl-2-hexenoic acid has been identified as the principal compound responsible for the smell of human sweat.

26-12 CONCEPT ASSESSMENT

Draw the structure of (*E*)-3-methyl-2-hexenoic acid.

Some properties of carboxylic acids can be rationalized in terms of the ability of carboxylic acid molecules to form hydrogen bonds among themselves or with other molecules (such as water). For example, low-molecular-weight carboxylic acids are soluble in water because of their ability to hydrogen bond with water. Also, carboxylic acids also have relatively high melting and boiling points because of hydrogen bonding.

As discussed in Chapter 16, soluble carboxylic acids behave as weak acids when they dissolve in water. A simple way to test whether a compound is a carboxylic acid is to add it to an aqueous solution of sodium hydrogen carbonate, $NaHCO_3(aq)$, or sodium carbonate, $Na_2CO_3(aq)$. If the compound is an acid, bubbles of $CO_2(g)$ will be visible because of the following reaction. For example,

$$2\,RCOOH(aq) + Na_2CO_3(aq) \longrightarrow 2\,RCOONa(aq) + CO_2(g) + H_2O(l) \qquad \textbf{(26.15)}$$

Preparation and Uses of Carboxylic Acids Carboxylic acids can be obtained in the laboratory by the oxidation of a primary alcohol or an aldehyde. For this purpose, the oxidizing agent is generally $KMnO_4(aq)$ in an alkaline medium. Because the medium is alkaline, the product is the potassium salt, but the free carboxylic acid can be regenerated by making the medium acidic.

$$CH_3CH_2OH \xrightarrow[OH^-,\ heat]{KMnO_4} CH_3COO^-K^+ \xrightarrow{H^+} CH_3COOH + K^+ \qquad \textbf{(26.16)}$$

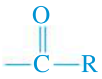
$$CH_3CH_2CH_2OH \xrightarrow[OH^-,\ heat]{KMnO_4} CH_3CH_2COO^-K^+ \xrightarrow{H^+} CH_3CH_2COOH + K^+ \qquad \textbf{(26.17)}$$

We have seen (earlier in this section) that primary alcohols and aldehydes can be oxidized to carboxylic acids. Carboxylic acids can also be prepared by the hydrolysis of nitriles. The hydrolysis of a nitrile can be carried out in either acidic or basic solution, as suggested below:

$$R{-}C{\equiv}N + 2\,H_2O \xrightarrow[\Delta]{H^+\ or\ OH^-} RCOOH + NH_3$$

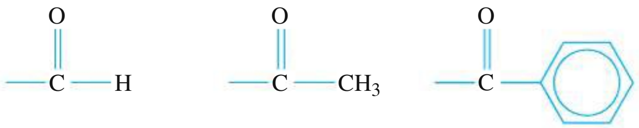
If the reaction is carried out in basic solution, the carboxylate anion, $RCOO^-$, is produced. To obtain RCOOH, the solution must be acidified.

Carboxylic acids are used extensively in organic chemistry to make other compounds and we will examine some of these reactions next (and in Chapter 27). Because many derivatives of carboxylic acids involve simple replacement of the hydroxyl groups, the following grouping of atoms is encountered frequently:



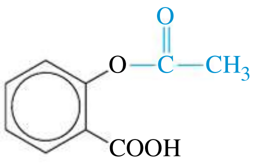
$$-\overset{\overset{\displaystyle O}{\|}}{C}-R$$

The grouping above is called an *acyl group*. The names of acyl groups are derived from the acid names by replacing *-ic acid* with the suffix *-yl*, as shown below:



IUPAC name:	Methanoyl (from methanoic acid)	Ethanoyl (from ethanoic acid)	Benzoyl (from benzoic acid)
Common name:	Formyl (from formic acid)	Acetyl (from acetic acid)	Benzoyl

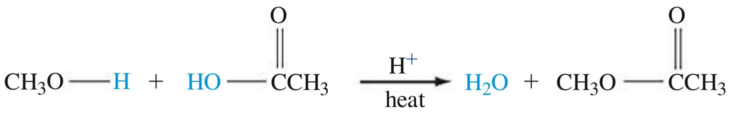
The IUPAC names for these acyl groups are almost never used. The acetyl derivative of *o*-hydroxybenzoic acid (salicylic acid) is what we know as ordinary aspirin, acetylsalicylic acid (ASA), the structure of which is shown in the margin.



Acetylsalicylic acid
(aspirin)

Esters

As shown in Table 26.2, the general formula of an ester is RCOOR′. Comparing the general formula of an ester with that of a carboxylic acid, we see that an **ester** is a molecule in which the hydroxyl group (—OH) of a carboxylic acid functional group is replaced by an alkoxyl group (—OR′). In the lab, esters can be prepared by the reaction of a carboxylic acid and an alcohol. The products of the reaction are an ester and a water molecule.



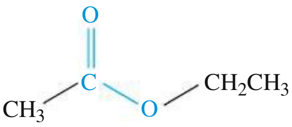
$$\mathrm{CH_3O{-}H} + \mathrm{HO{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{CH_3} \xrightarrow[\text{heat}]{\mathrm{H^+}} \mathrm{H_2O} + \mathrm{CH_3O{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{CH_3} \qquad \mathbf{(26.18)}$$

Methanol (methyl alcohol) Ethanoic acid (acetic acid) Methyl ethanoate (methyl acetate)

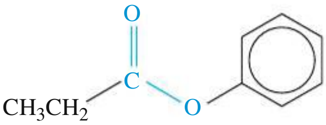
Because the reaction above is reversible, an excess of alcohol is often used to ensure a high yield of the ester.

Esters have two-part names. The first part is the alkyl designation of the —OR′ group. The second part is the carboxylic acid name with *-ic acid* changed to *-ate*. For example, the combination based on ethanoic acid and the methoxy group is *methyl ethanoate*. A few more examples are shown here.

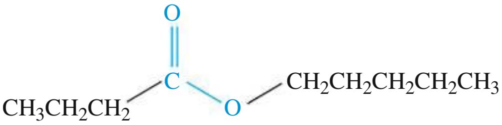
▲ The distinctive aroma and flavor of oranges are due in part to the ester octyl acetate, $CH_3(CH_2)_6CH_2OOCCH_3$.



Ethyl ethanoate
(ethyl acetate)



Phenyl propanoate
(phenyl propionate)

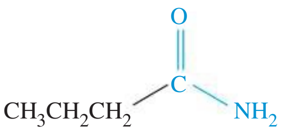


Pentyl butanoate
(pentyl butyrate)

Unlike the pungent odors of the carboxylic acids from which they are derived, esters have very pleasant aromas. The characteristic fragrances of many flowers and fruits can be traced to the esters they contain. Esters are used in perfumes and in the manufacture of flavoring agents for the confectionery and soft drink industries. Most esters are colorless liquids that are insoluble in water. Their melting points and boiling points are generally lower than those of alcohols and acids of comparable carbon content. This is because of the absence of hydrogen bonding in esters.

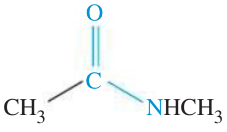
Amides

The replacement of the hydroxyl group in the carboxylic acid functional group with an $-NH_2$ group produces an **amide**. For example, the molecule butanamide (shown in margin) is formed by replacing the hydroxyl group in ethanoic acid by the $-NH_2$ group.

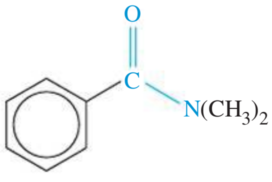


Butanamide

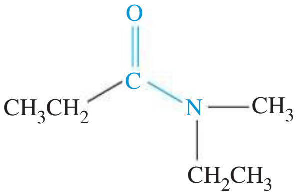
The name of an amide is constructed from the alkane part of the acid name and the suffix *-amide* is added. If hydrogen atoms on the nitrogen atom are replaced with other groups, then a substituted amide is obtained. For example, in the molecules below, one or both of the H atoms in the $-NH_2$ group of ethanamide have been replaced by other groups. Here are a few examples.



N-methylethanamide

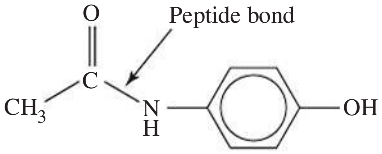


N,*N*-dimethylbenzamide



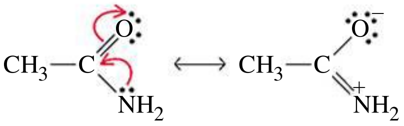
N-ethyl-*N*-methylpropanamide

As the examples above show, we name a substituted amide by using the prefix *N*- in front of each nitrogen substituent. The replacement of one H atom gives a *N*-substituted amide. The active ingredient in Tylenol® is an *N*-substituted amide (see margin). The $-CO-NH-$ linkage present in *N*-substituted amides is called a *peptide bond*, and it is a key bond type in proteins, as we will discover in Chapter 28.



N-(4-hydroxyphenyl)ethanamide
(Tylenol®)

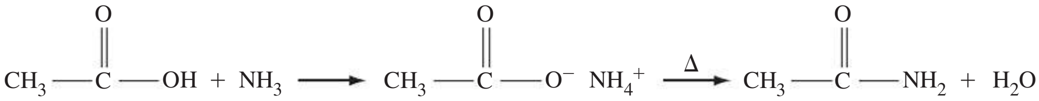
Despite the presence of the $-NH_2$ group in simple amides, they are not Brønsted bases like amines or ammonia because the carbonyl group promotes the resonance structures shown below.



◀ Resonance in an amide.

The lone pair of electrons on the nitrogen atom is delocalized over the carbonyl group toward the more electronegative oxygen atom. In fact, as seen from the resonance structures, it is the carbonyl group that is most likely to be protonated in acidic conditions. The protonation of the oxygen in a carbonyl group is often an important first step in reactions of esters and amides under acidic conditions.

Preparation and Uses of Amides One way of making an amide is to treat a carboxylic acid with ammonia, forming an ammonium salt, followed by heating. The following sequence summarizes a pathway for making ethanamide.



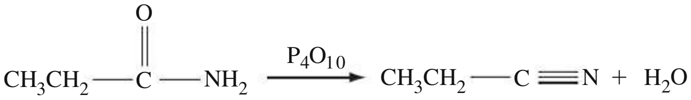
$$CH_3-\overset{O}{\overset{\|}{C}}-OH + NH_3 \longrightarrow CH_3-\overset{O}{\overset{\|}{C}}-O^- \; NH_4^+ \xrightarrow{\Delta} CH_3-\overset{O}{\overset{\|}{C}}-NH_2 + H_2O$$

(26.19)

However, amides are seldom prepared as described above. As we will see in Chapter 27, a more effective way of converting CH_3COOH to CH_3CONH_2 is to treat the acid with $SOCl_2$ first, which converts the acid to a more reactive *acid chloride* (CH_3COCl), and then treat the acid chloride with ammonia.

Amides can be converted into other compounds, but compared with other carboxylic acid derivatives, amides are relatively unreactive. The stability of biological structures and the properties of *polyamides*, such as silk and nylon, depend, in part, on the presence of amide linkages. Amides can, however, be converted into nitriles, R—C≡N, using a strong dehydrating agent such as P_4O_{10}.

▶ A polyamide is a polymer of amides joined by peptide bonds. Polymers are discussed in Chapter 27.



$$CH_3CH_2-\overset{\overset{\displaystyle O}{\|}}{C}-NH_2 \xrightarrow{P_4O_{10}} CH_3CH_2-C\equiv N + H_2O$$

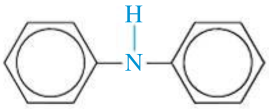
Amides are also routinely used to make amines, a class of compounds we discuss next.

Amines

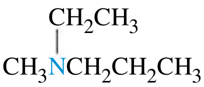
Amines are organic derivatives of ammonia, NH_3, in which one or more organic groups (R) are substituted for H atoms. Their classification is based on the number of R groups bonded to the nitrogen atom—one for primary amines, two for secondary, and three for tertiary (see margin). One of the chief methods of preparing an amine is by the reduction of a nitro compound.

$CH_3CH_3NH_2$

Ethylamine
(a primary amine)

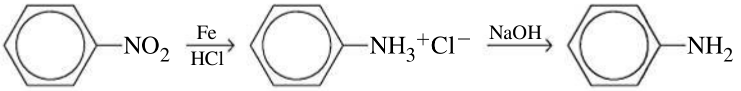


Diphenylamine
(a secondary amine)



$$CH_3\underset{}{\overset{\overset{\displaystyle CH_2CH_3}{|}}{N}}CH_2CH_2CH_3$$

Ethylmethylpropylamine
(a tertiary amine)

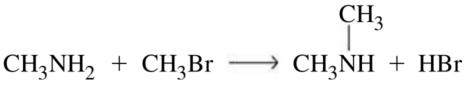


(26.20)

An alternative method of preparing an amine involves the reaction of ammonia with an alkyl halide. The methylammonium bromide formed reacts with additional ammonia to give the amine.

$$NH_3 + CH_3Br \longrightarrow CH_3NH_3{}^+Br^-$$
$$CH_3NH_3{}^+Br^- + NH_3 \longrightarrow CH_3NH_2 + NH_4{}^+Br^-$$

The formation of pure primary amines is difficult by this method because when the primary amine is formed, it can take part in a further substitution reaction with the alkyl halide to form a secondary amine, for example,

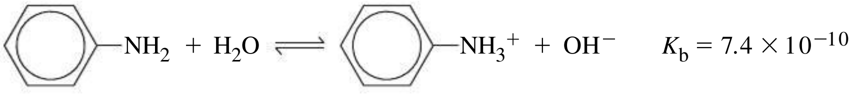


$$CH_3NH_2 + CH_3Br \longrightarrow CH_3\overset{\overset{\displaystyle CH_3}{|}}{N}H + HBr \qquad \textbf{(26.21)}$$

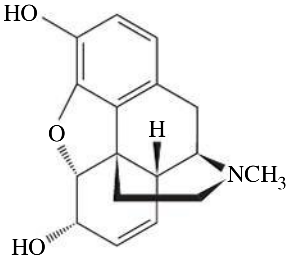
The compound formed here is dimethylamine. Further reaction with bromomethane produces the tertiary amine, trimethylamine.

Amines of low molecular mass are gases that are readily soluble in water, yielding basic solutions. The volatile members have odors similar to ammonia, but more fish-like. Primary and secondary amines form hydrogen bonds, but these bonds are weaker than those in water because nitrogen is less electronegative than oxygen. Like ammonia, amines have trigonal pyramidal structures with a lone pair of electrons on the N atom. Also like ammonia, amines owe their basicity to these lone-pair electrons. In aromatic amines, because of unsaturation in the benzene ring, electrons are drawn into the ring, which reduces the electron charge density on the nitrogen atom. As a result, aromatic amines are *weaker* bases than ammonia. Aliphatic amines are somewhat stronger bases than ammonia.

$$NH_3 + H_2O \rightleftharpoons NH_4{}^+ + OH^- \qquad K_b = 1.8 \times 10^{-5}$$
$$\underset{\text{methylamine}}{CH_3NH_2} + H_2O \rightleftharpoons CH_3NH_3{}^+ + OH^- \qquad K_b = 42 \times 10^{-5}$$



aniline



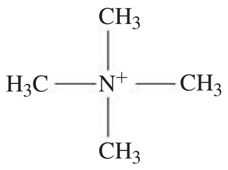
Morphine

▲ Morphine, a very powerful and addictive painkiller, can be isolated from the opium poppy (*Papaver somniferum*).

Dimethylamine is an accelerator for the removal of hair from hides in the processing of leather. Butyl- and pentylamines are used as antioxidants, corrosion inhibitors, and in the manufacture of oil-soluble soaps. Dimethylamine and trimethylamine are used in the manufacture of ion-exchange resins. Additional applications are found in the manufacture of disinfectants, insecticides, herbicides, drugs, dyes, fungicides, soaps, cosmetics, and photographic developers. Many amines demonstrate biological activity, including cocaine, nicotine, morphine (see margin, previous page), quinine, and vitamin B6, to name just a few.

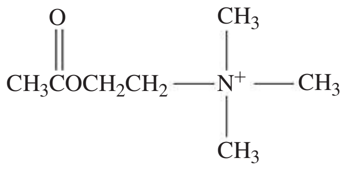
Important derivatives of ammonia are the *tetraalkyl ammonium salts*. The cation in these salts has four organic groups attached to the nitrogen atom and is called a *quaternary ammonium ion*. In a quaternary ammonium ion, the nitrogen atom has a formal charge of 1+. Two examples of such cations are shown in the margin.

The acetylcholine cation is similar to the much simpler tetramethylammonium cation, except that one of the methyl groups has been replaced by a $CH_3COOCH_2CH_2$— group. Quaternary ammonium ions, such as acetylcholine, are involved in the systems that transmit nerve impulses in the human body. Also, many poisons that affect the central nervous system contain a quaternary ammonium functional group.



$$H_3C-\overset{CH_3}{\underset{CH_3}{N^+}}-CH_3$$

Tetramethylammonium ion



$$CH_3\overset{O}{\overset{\|}{C}}OCH_2CH_2-\overset{CH_3}{\underset{CH_3}{N^+}}-CH_3$$

Acetylcholine

Heterocyclic Compounds

In most of the ring structures considered to this point, all the ring atoms have been carbon; these structures are said to be carbocyclic. However, in many compounds, both natural and synthetic, one or more of the atoms in a ring structure is not carbon. These ring structures are said to be **heterocyclic**. The heterocyclic systems most commonly encountered contain N, O, and S atoms, and the rings are of various sizes.

Pyridine is a nitrogen analogue of benzene (Fig. 26-17). Unlike benzene, it is water soluble and has basic properties (the unshared pair of electrons on the N atom is not part of the π electron cloud of the ring system). Pyridine, a liquid with a disagreeable odor, was once obtained exclusively from coal tar, but it is now used so extensively that several synthetic methods have been developed for its production. It is used in the production of pharmaceuticals such as sulfa drugs and antihistamines, as a denaturant for ethyl alcohol, as a solvent for organic chemicals, and in the preparation of waterproofing agents for textiles. A number of other examples of heterocyclic compounds are discussed in Chapter 28.

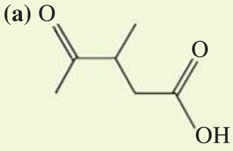
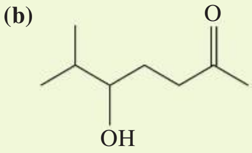
26-1 ARE YOU WONDERING...

How to name compounds with more than one functional group?

In our discussion of organic compounds we restricted our discussion to molecules with only one functional group. How do we name the following compounds, each of which has more than one functional group?





(continued)

The IUPAC rules provide a solution to this problem by assigning priorities to functional groups. The priorities of some of the common functional are as follows:

carboxylic acid > ester > amide > aldehyde >
Highest priority
ketone > alcohol > amine > alkoxy
Lowest priority

Notice that functional groups with two heteroatoms (carboxylic acids, esters, and amides) have higher priorities than do those with only one heteroatom.

The priority order enables us to decide that molecule (a) is an acid, in fact a pentanoic acid. But what prefix do we use for the carbonyl group? The prefix *oxo-* is used to indicate either an aldehyde or a ketone as a substituent. We name the molecule 3-methyl-4-oxopentanoic acid.

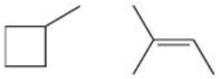
The prefixes for the —OH and —NH_2 substituents are *hydroxy* and *amino* respectively. Thus, the name of molecule (b) is 5-hydroxy-6-methyl-2-heptanone.

A more complete discussion of nomenclature is normally covered in more advanced organic chemistry courses.

26-8 From Molecular Formula to Molecular Structure

Given only a molecular formula (perhaps derived from an experimentally determined percentage composition and a molecular weight determination) and some chemical evidence that suggests what functional groups might be present, how might we proceed to propose a possible structure?

First, it is helpful to determine how many elements of unsaturation are in a molecule. An element of unsaturation is a structural feature, such as a carbon–carbon double or triple bond or a ring structure, that causes the number of hydrogen atoms in a molecule to be less than the maximum number possible. We have learned that a saturated hydrocarbon with n carbon atoms has $2n + 2$ hydrogen atoms, the maximum number possible. We have also learned that the general formula is C_nH_{2n} for a simple alkene (a hydrocarbon having only one double bond) or a cycloalkane. Thus, a simple alkene or a cycloalkane has two fewer H atoms than the maximum number possible. We conclude that the number of H atoms decreases by two for each carbon–carbon π bond or ring structure that is present. Consider, for example, a molecule with the formula C_5H_{10}. The molecule has two fewer hydrogen atoms than the maximum possible and it could be one of the following molecules. (There are other isomers too. Try to draw structures for them.)



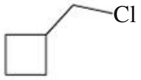
Each of these molecules contains one structural element (a π bond or a ring structure) that contributes to it being unsaturated. For each of these structures, the **degree of unsaturation** is equal to one. When the degree of unsaturation is equal to one, there will be two fewer H atoms than the maximum possible. When there are four hydrogen atoms less than the maximum, the degree of unsaturation is two.

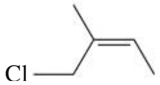
KEEP IN MIND

that benzene, C_6H_6, has eight fewer H atoms than the maximum possible. Thus, the degree of unsaturation associated with a benzene ring is four, a result which is consistent with one ring plus the equivalent of three delocalized π bonds. A high degree of unsaturation is often accounted for by a benzene ring.

If an organic molecule with n carbon atoms has fewer than $2n + 2$ hydrogen atoms, then it contains elements of unsaturation, such as π bonds or ring structures.

Up to this point, we have focused on molecules containing only carbon and hydrogen. The determination of the degree of unsaturation in molecules containing O, N, or Cl atoms requires some explanation. In organic compounds, halogen atoms, such as chlorine, are typically terminal atoms, not central atoms. In this regard, halogen atoms are similar to hydrogen atoms. When determining the degree of unsaturation, halogen atoms are counted as if they were hydrogen atoms. Stated another way, each halogen atom effectively adds one hydrogen to the hydrogen count. Thus, C_5H_9Cl has one degree of unsaturation because 9 + 1 is two less than the maximum number of hydrogen atoms possible. Some possible structures for C_5H_9Cl are shown below. (Again, there are other possible structures. Draw structures for the other isomers.)

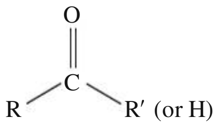




Now let us consider the situations that can arise if oxygen atoms are present in a molecule. It turns out that the degree of unsaturation in a carbon–hydrogen–oxygen compound can be established by considering only the number of carbon and hydrogen atoms in the molecule; that is, we can ignore the oxygen atoms. To understand why, let's consider a molecule that contains only one oxygen atom. The following linkages are possible:

Alcohol

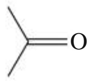
Ether



Ketone (or aldehyde)

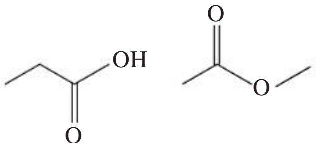
For an alcohol or ether, we see that the oxygen atom is inserted either between a carbon atom and a hydrogen atom or between two carbon atoms. Neither of these linkages causes a decrease in the number of hydrogen atoms and thus, neither is considered an element of unsaturation. Turning this idea around, we can say that if the formula of a molecule is $C_nH_{2n+2}O$, then it must be an alcohol or an ether with no π bonds or ring structures. In a carbonyl compound, however, the oxygen atom takes the place of two hydrogen atoms. Thus, a carbonyl compound has one element of unsaturation and a general formula of $C_nH_{2n}O$.

To illustrate these ideas, consider a molecule having the formula C_3H_6O. For three carbon atoms, the maximum number of hydrogen atoms is eight. Ignoring the oxygen atom, we see that the number of hydrogen atoms is two less than the maximum, and so there is one degree of unsaturation. Three possible isomers are shown below. (Try to identify and draw structures for the other isomers.)



Now consider the molecule C_3H_8O. Ignoring the oxygen atoms, we determine that there are no elements of unsaturation. Consequently, there are no π bonds or rings in the molecule. Two possible isomers are shown below:

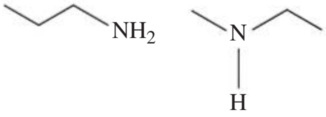
The ideas discussed above are easily extended to molecules containing more than one oxygen atom. For example, let us consider a molecule with the formula $C_3H_6O_2$. Again, in determining the degree of unsaturation, we ignore the oxygen atoms. Because there are only six hydrogen atoms and not eight, we conclude that the degree of unsaturation is one. Two possible isomers are a carboxylic acid or an ester, which are shown below:



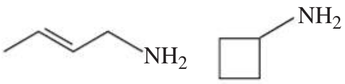
26-13 CONCEPT ASSESSMENT

Is it possible one of the isomers of $C_3H_6O_2$ is a dialdehyde?

Nitrogen atoms also appear in organic compounds. How do we deal with a nitrogen atom in determining the degree of unsaturation? Let's consider the molecule C_3H_9N. Two isomers are shown below:



Both molecules are saturated and contain the maximum number of hydrogen atoms possible. How can we deduce the degree of unsaturation from the formula of this molecule? The key idea is that for each nitrogen atom present in the formula, the hydrogen atom count is diminished by one. Thus, the number of H atoms in C_3H_9N is considered to be 8 (not 9), which is equal to the number of H atoms expected in a saturated molecule containing three carbon atoms. For a compound with the formula C_4H_9N, the number of H atoms is effectively 8. A saturated molecule containing 4 carbon atoms should contain $2 \times 4 + 2 = 10$ hydrogen atoms. Because the molecule effectively contains only 8 hydrogen atoms (two less than the maximum), we know the degree of unsaturation is one. Two possible isomers for C_4H_9N are shown below:



EXAMPLE 26-10 Determining the Degree of Unsaturation and Suggesting Possible Structures for a Molecule

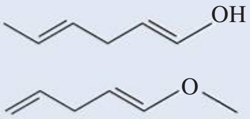
What different types of compounds are possible for a compound with the molecular formula $C_6H_{10}O$?

Analyze

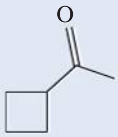
We need to establish the degree of unsaturation in the molecule and then construct one example of each type of molecule that can be formed.

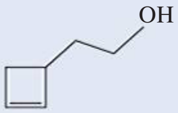
Solve

As we described above, we can ignore the oxygen atom in determining the degree of unsaturation. The maximum number of hydrogen atoms is $2 \times 6 + 2 = 14$. The molecular formula has only 10 hydrogen atoms, so we know the degree of unsaturation is two. What types of molecules can be formed? We might start by considering dienes with either an alcohol or an ether functional group.

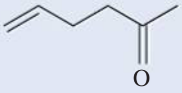


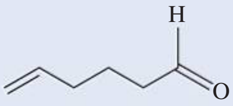
Alternatively, we can have a cyclic alkane with a carbonyl group or a cyclic alkene with an alcohol functional group. Two possible structures are shown here.





Two other possibilities are a ketone with an alkene side chain or an aldehyde with an alkene side chain. Two possible structures are shown here.





Assess

We have provided an example of an ether (with two degrees of unsaturation in the alkane chain), an aldehyde (with one degree of unsaturation in a side chain), a ketone, and some alcohols. This list is not exhaustive and you should be able to find other isomers.

PRACTICE EXAMPLE A: What different types of compounds are obtainable for a compound with the molecular formula $C_5H_{11}N$?

PRACTICE EXAMPLE B: What different types of compounds are obtainable for a compound with the molecular formula $C_5H_{10}O_2$?

www.masteringchemistry.com

Obtaining enantiomerically pure samples of chiral molecules is extremely important when synthesizing pharmaceuticals. When a synthesis yields a mixture of enantiomers, the enantiomers may be separated from each other using a process called chemical resolution. For a discussion of this method, go to the Focus On feature for Chapter 26, Chemical Resolution of Enantiomers, on the MasteringChemistry site.

Summary

26-1 Organic Compounds and Structures: An Overview—Organic chemistry deals with compounds of carbon, the simplest of which, called **hydrocarbons**, contain only carbon and hydrogen atoms. The carbon atoms are bonded to one another in straight- or branched-chains or in rings. In **saturated hydrocarbons** all chemical bonds are single bonds. Isomers that differ in their structural skeletons are **constitutional isomers**. Alkane substituents that branch off a main hydrocarbon chain are called **alkyl groups** (Table 26.1). Carbon atoms in alkane chains are classified as **primary**, **secondary**, **tertiary**, and **quaternary** depending on the number of carbon atoms attached to them. Hydrogen atoms are similarly classified depending on the type of carbon atom to which they are attached; for example, hydrogen atoms attached to a primary carbon atom are called **primary hydrogen atoms**. A systematic nomenclature based on IUPAC rules is used to name alkanes. Distinctive groupings of atoms are referred to as **functional groups** (Table 26.2). Organic compounds are typically classified according to their functional groups. A three-dimensional representation of hydrocarbons can be accomplished using the **dashed and solid wedge line notation**. In this notation, solid lines represent bonds in the plane of the paper, solid wedges show bonds sticking out toward the viewer, and dashed wedges show bonds directed away from the viewer.

26-2 Alkanes—Among saturated hydrocarbons, also known as **alkanes**, those based on a straight- or branched-chains of carbon atoms have the formula C_nH_{2n+2} and are called **aliphatic** hydrocarbons. Aliphatic hydrocarbons that differ in sequence by a constant unit form a **homologous series**. Hydrocarbons can adopt different **conformations**, or arrangements, of their atoms. Aliphatic hydrocarbons have eclipsed and staggered conformations. Newman projections are used to depict these conformations (Figure 26-6). The energy difference between the eclipsed and staggered forms of an alkane is called the **torsional energy**. The variation in potential energy as one end of the molecule is rotated with respect to the other can be displayed in the form of a potential energy diagram (Fig. 26-8). The preference for certain conformations is driven in part by steric interactions involving bulky groups. In butane, for example, the **anti** conformation is lower in energy than the **gauche** conformation. The principal natural sources of alkanes are natural gas and petroleum.

26-3 Cycloalkanes—Hydrocarbons that form ring structures are termed **alicyclic**. Ring strain exists in cycloalkanes containing 3, 4, and 5 carbon atoms. A study of heats of combustion shows that cyclohexane is strain free. Disubstituted cycloalkanes exhibit a form of **stereoisomerism** known as

***cis–trans* isomerism**. Cyclohexanes undergo rapid ring flips (Fig. 26-13). In substituted cyclohexanes, substituents compete for the equatorial positions.

26-4 Stereoisomerism in Organic Compounds—A carbon atom that is bonded to four different groups is called an **asymmetric** carbon atom. An asymmetric carbon atom is also called a **stereocenter**. A molecule containing an asymmetric carbon atom is not superimposable on its mirror image and is **chiral**. Chiral molecules are optically active—they rotate the plane of polarized light. Molecules with superimposable mirror images are **achiral**. Molecules with sp^3 stereocenters are named by using the ***R*, *S* system**. The rules for an *R*, *S* designation require assigning priorities to the substituents on a chiral C atom and "reading" the descending priority order of the substituents when the molecule is viewed in a particular orientation. If the descending priority order is clockwise, the molecule is *R*; if it is counterclockwise, the molecule is *S*. The two molecules with *R* and *S* configurations are known as **enantiomers**. Stereoisomers that are not enantiomers are called **diastereomers**. *Cis* and *trans* isomers are examples of diastereomers.

26-5 Alkenes and Alkynes—Hydrocarbons whose molecules contain fewer hydrogen atoms than found in the corresponding alkane are **unsaturated** hydrocarbons. The unsaturation arises because of the presence of one or more carbon-to-carbon double or triple bonds. Hydrocarbons containing one or more double bonds are **alkenes**, or **olefins**, whereas those containing one or more triple bonds are **alkynes**. The placement of double or triple bonds in an unsaturated hydrocarbon can lead to different constitutional isomers, as in 2-butene versus 1-butene, for example. In 2-butene the orientation of the two end methyl groups leads to *cis* and *trans* isomers, a type of isomerism called *cis–trans* isomerism. Highly substituted alkenes are named by the ***E*, *Z* system**. Molecules are given the *Z* designation when higher priority substituents at each end of a double bond are on the same side of the double bond and the *E* designation when they are on opposite sides of the double bond.

26-6 Aromatic Hydrocarbons—Many unsaturated hydrocarbons with ring structures are classified as **aromatic hydrocarbons**; most are based on the benzene molecule, C_6H_6. Two systems are commonly used to name substituents on a benzene ring. One uses a numbering system, such as 1,2-dichlorobenzene. The other uses the relative positions of substituents. Substituents on adjacent carbon atoms are referred to as **ortho (*o*)**; substituents separated by one carbon are **meta (*m*)**; and substituents opposite each other on the ring are **para (*p*)**. A **phenyl** group is a benzene ring with one hydrogen atom removed. A **benzyl** group is a methyl group with one hydrogen atom replaced by a phenyl group.

26-7 Organic Compounds Containing Functional Groups—*Alcohols and phenols:* Hydrocarbons that contain an —OH (**hydroxyl**) group are classified as **alcohols** in aliphatic compounds and **phenols** in aromatic compounds. Aliphatic alcohols are also classified as primary, secondary, or tertiary, depending on how many other substituents (excluding H atoms) are attached to the same carbon atom as the hydroxyl group: one for primary, two for secondary, and three for tertiary. Diols and polyols are molecules with two or more hydroxyl groups, respectively.

Ethers: The general formula of an **ether** is R—O—R′. The ether linkage is very stable and ethers are generally unreactive, resistant to both oxidation and reduction. One of the major uses of ethers is as solvents.

Aldehydes and ketones: The **carbonyl group** has a carbon atom attached by a double bond to an oxygen atom. If one of the two substituents attached to the carbonyl group is an H atom, the compound is an **aldehyde**, otherwise it is a **ketone**. In IUPAC nomenclature, the suffix *-al* is used for aldehydes and *-one* for ketones.

Carboxylic acids: The **carboxyl group** is a combination of the carbonyl and hydroxyl groups. **Carboxylic acids** have the general formula RCOOH and can be prepared by the oxidation of aldehydes. An acetyl group results when the —OH of a carboxyl group is replaced by a methyl group.

Esters: An **ester** is formed when an alkoxy group replaces the —OH of a carboxyl group. The general formula of an ester is RCOOR′. Most esters are colorless liquids that are insoluble in water and have pleasant fragrances.

Amides: The general formula of a primary **amide** is $RCONH_2$. A primary amide has two H atoms bonded to N and results when the hydroxyl group of a carboxylic acid is replaced by $—NH_2$. In secondary or tertiary amides, one or two H atoms in the $—NH_2$ are replaced by alkyl or aryl groups. Because of resonance, amides are much weaker bases than are ammonia or amines.

Amines: **Amines** are organic derivatives of ammonia. They are classified according to the number of organic groups (R) substituted for hydrogen atoms in NH_3. A primary amine has one substituent; a secondary amine, two substituents; and a tertiary amine, three substituents. Amines are weak bases, with the aliphatic amines being stronger bases than ammonia and the aromatic amines being weaker. Tetraalkyl ammonium salts are organic derivatives of the ammonium cation with a suitable anion.

Heterocyclic compounds: In a **heterocyclic compound**, at least one of the ring atoms is a heteroatom (not carbon). The most common heteroatoms are N, O, and S. Heterocyclic compounds tend to be more soluble in water than the parent compound because of the polarity of the heterocycle.

26-8 From Molecular Formula to Molecular Structure—A useful idea in determining a suitable structure is the **degree of unsaturation**, which is equal to the total number of π bonds and ring structures in a molecule. The degree of unsaturation is determined by comparing the number of H atoms in the molecule to the maximum number possible for the number of carbon atoms present. In counting the number of H atoms in a molecule, each halogen atom effectively increases the hydrogen count by one; oxygen atoms can be ignored; and each nitrogen atom, in effect, decreases the hydrogen atom count by one.

Integrative Example

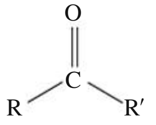
An acyclic organic compound with the formula $C_6H_{12}O$ is found to be optically active, does not decolorize Br_2 (in CCl_4), and does not undergo reaction when treated with a mixture of $Na_2Cr_2O_7$ and H_2SO_4. However, a reaction does occur when the compound is treated with $NaBH_4$. Identify a compound having these physical and chemical properties. Then draw structures for the two stereoisomers, using dashed and solid wedge symbols. Finally, give acceptable names for the two stereoisomers.

Analyze

There is only one oxygen atom per molecule, so the compound must be an alcohol, ether, aldehyde, or ketone. Also, because there are only 12 hydrogen atoms per molecule, rather than $2 \times 6 + 2 = 14$, we know that the molecule must contain either a π bond or a ring. We are told the compound is acyclic, and thus the molecule must contain a π bond and not a ring. Alcohols (except tertiary alcohols) and aldehydes are rather easily oxidized, so we suspect the molecule is neither an alcohol (though possibly a tertiary alcohol) nor an aldehyde. The ether linkage is stable in the presence of most oxidizing and reducing agents, and because the compound we need can be reduced, we suspect that that the compound is not an ether. At this point, we must decide whether the molecule is a ketone or a tertiary alcohol containing a carbon–carbon double bond. We can rule out a carbon–carbon double bond because the compound does not react with Br_2, a reaction characteristic of alkenes. The compound we seek is a ketone.

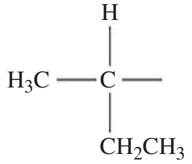
Solve

We have reasoned that the compound is a ketone. The linkage associated with a ketone is

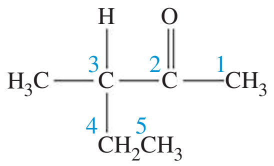


The five remaining carbon atoms are distributed among the two alkyl groups. The carbon of a carbonyl group is bonded to only three groups, and thus it cannot be chiral. The chiral carbon is part of one of the alkyl groups. Both R and R′ must contain at least one carbon atom and so, the maximum number of carbon atoms in R or R′ is four.

Let's choose R to be the alkyl group that contains the chiral carbon. A chiral carbon atom must be bonded to four different groups and yet R contains no more than four carbon atoms. The only possibility for R is

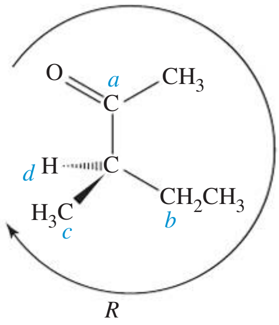


We have accounted for five of the six carbon atoms (R contains four carbon atoms and the carbonyl group contains one). Thus, R′ represents a methyl group. A skeletal structure for the molecule is

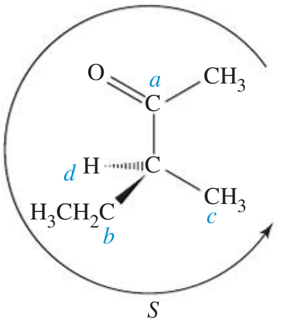


3-methyl-2-pentanone

The longest carbon chain has five carbon atoms with a carbonyl group bonded to C2 and a methyl group bonded to C3. The molecule is 3-methyl-2-pentanone. Because C3 is chiral, two enantiomers are possible.



(*R*)-3-methyl-2-pentanone



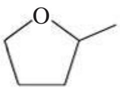
(*S*)-3-methyl-2-pentanone

Assess

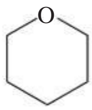
It may not be obvious that there is only one possibility for R. Try drawing structures of other ketones having the formula $C_6H_{12}O$ to convince yourself that there is only one possibility. Had we not been told the compound was acyclic, a unique identification would not have been possible.

PRACTICE EXAMPLE A: Compound A with the formula C_3H_8O is soluble in water and reacts with sodium metal, producing bubbles of gas. When compound A is treated with chromic acid (a mixture of $Na_2Cr_2O_7$ and H_2SO_4), compound B is formed. Compound B dissolves readily in $Na_2CO_3(aq)$ and reacts with ethanol, yielding compound C which has a fruity fragrance. Identify compounds A, B, and C.

PRACTICE EXAMPLE B: The following molecules all have the molecular formula $C_5H_{10}O$. You suspect that you have a sample of one of these compounds. What tests could you perform to ascertain which of these compounds you have?



(a)



(b)

(d)

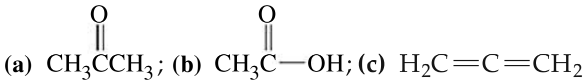
MasteringCHEMISTRY

You'll find a link to additional self study questions in the study area on www.masteringchemistry.com

Exercises

Organic Structures

1. Write structural formulas corresponding to these condensed formulas.
   (a) $CH_3CH_2CHBrCHBrCH_3$
   (b) $(CH_3)_3CCH_2C(CH_3)_2CH_2CH_2CH_3$
   (c) $(C_2H_5)_2CHCH{=}CHCH_2CH_3$
2. Draw a structural formula for each of the following compounds.
   (a) 3-isopropyloctane; **(b)** 2-chloro-3-methylpentane; **(c)** 2-pentene; **(d)** dipropyl ether.
3. Supply a structural formula for each of the following compounds.
   (a) 1,3,5-trimethylbenzene; **(b)** *p*-nitrophenol; **(c)** 3-amino-2,5-dichlorobenzoic acid (a plant-growth regulator).
4. Write structural formulas corresponding to these condensed formulas.
   (a) $(CH_3)_3CCH_2CH(CH_3)CH_2CH_2CH_3$
   (b) $(CH_3)_2CHCH_2C(CH_3)_2CH_2Br$
   (c) $Cl_3CCH_2CH(CH_3)CH_2Cl$
5. Draw Lewis structures of the following simple organic molecules: **(a)** $CH_3CHClCH_3$; **(b)** $HOCH_2CH_2OH$; **(c)** CH_3CHO.
6. Draw Lewis structures of the following simple organic molecules: **(a)** CH_3CH_2COOH; **(b)** H_3CCN; **(c)** $CH_3CH_2NH_2$.
7. With appropriate sketches, represent chemical bonding in terms of the overlap of hybridized and unhybridized atomic orbitals in the following molecules.
   (a) C_4H_{10}; **(b)** $H_2C{=}CHCl$; **(c)** $CH_3C{\equiv}CH$
8. With appropriate sketches, represent chemical bonding in terms of the overlap of hybridized and unhybridized atomic orbitals in the following molecules.



(a) $CH_3\overset{\overset{\displaystyle O}{\|}}{C}CH_3$; **(b)** $CH_3\overset{\overset{\displaystyle O}{\|}}{C}{-}OH$; **(c)** $H_2C{=}C{=}CH_2$

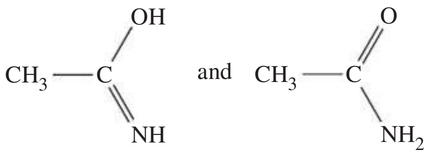
Isomers

9. What is the relationship, if any, between the molecules in each of the following pairs? The relationship may be any of identical structures, constitutional isomers, stereoisomers, or no relationship.

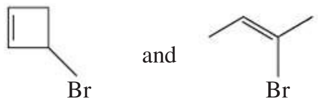
(a)

$CH_3CH_2CH_2Cl$ and $ClCH_2CH_2CH_3$

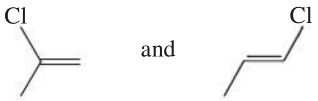
(b)



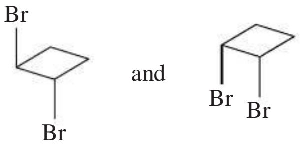
(c)



(d)

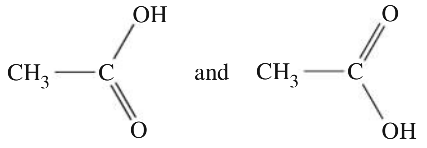


(e)

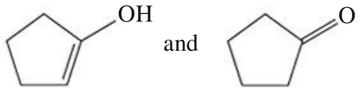


10. What is the relationship, if any, between the molecules in each of the following pairs? The relationship may be any of identical structures, constitutional isomers, stereoisomers, or no relationship.

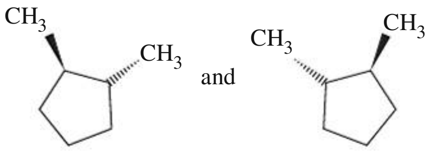
(a)



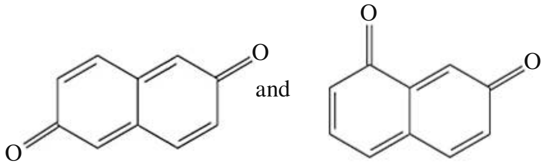
(b)



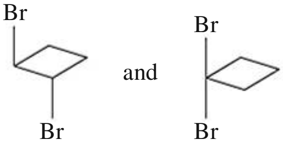
(c)



(d)



(e)

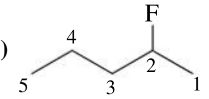


11. Draw structural formulas for all the isomers of C_7H_{16}.

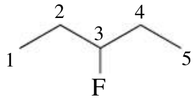
12. Draw and name all the isomers of **(a)** C_6H_{14}; **(b)** C_4H_8; **(c)** C_4H_6. [*Hint:* Do not forget double bonds, rings, and combinations of these.]

13. Identify the chiral carbon atoms, if any, in the following compounds.

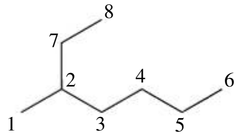
(a)



(b)

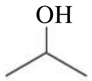


(c)

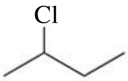


14. Identify the chiral carbon atoms, if any, in the following compounds.

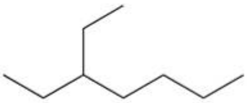
(a)



(b)

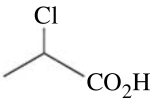


(c)

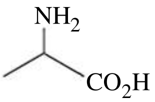


15. Identify the chiral carbon atoms, if any, in the following compounds.

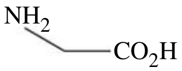
(a)



(b)

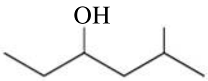


(c)

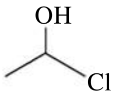


16. Identify the chiral carbon atoms, if any, in the following compounds.

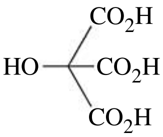
(a)



(b)



(c)



Functional Groups

17. Identify the functional group in each compound (i.e., alcohol, amine, etc.).
(a) $CH_3CHBrCH_2CH_3$
(b) $C_6H_5CH_2CHO$
(c) $CH_3COCH_2CH_3$
(d) $C_6H_4(OH)_2$

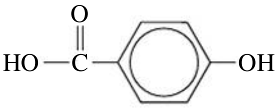
18. Identify the functional group in each compound (i.e., alcohol, amine, etc.).
(a) CH_3CH_2COOH
(b) $(CH_3)_2CHCH_2OCH_3$
(c) $CH_3CH(NH_2)CH_2CH_3$
(d) CH_3COOCH_3

19. The functional groups in each of the following pairs have certain features in common, but what is the essential difference between them?
(a) carbonyl and carboxyl
(b) aldehyde and ketone
(c) acetic acid and acetyl group

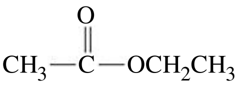
20. By name or formula, give one example of each of the following types of compounds: **(a)** aromatic nitro compound; **(b)** aliphatic amine; **(c)** chlorophenol; **(d)** aliphatic diol; **(e)** unsaturated aliphatic alcohol; **(f)** alicyclic ketone; **(g)** halogenated alkane; **(h)** aromatic dicarboxylic acid.

21. Identify and name the functional groups in each of the following.

(a)

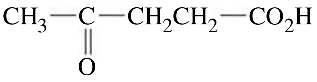


(b)



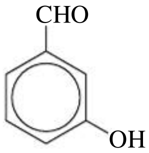
$CH_3-\overset{\overset{\displaystyle O}{\|}}{C}-OCH_2CH_3$

(c)



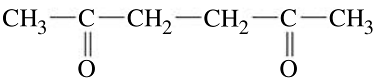
$CH_3-\underset{\underset{\displaystyle O}{\|}}{C}-CH_2CH_2-CO_2H$

(d)



22. Identify and name the functional groups in each of the following.

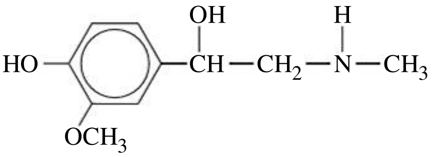
(a)



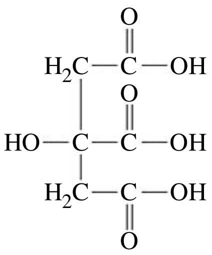
$CH_3-\underset{\underset{\displaystyle O}{\|}}{C}-CH_2-CH_2-\underset{\underset{\displaystyle O}{\|}}{C}-CH_3$

(b) $CH_3-CH_2-CONHCH_3$

(c)



(d)



23. Give the isomers of $C_4H_{10}O$ that are ethers.

24. Give the isomers of $C_5H_{12}O$ that are ethers.

25. Give the isomers of the carboxylic acid with molecular formula $C_5H_{10}O_2$.

26. Give the isomers of the carboxylic acid with the molecular formula $C_4H_8O_2$.

27. Give the isomers of the esters having the molecular formula $C_5H_{10}O_2$.

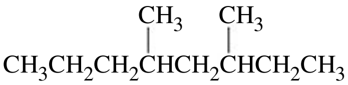
28. Give the isomers of the esters having the molecular formula $C_4H_8O_2$.

29. Give the noncyclic isomers with molecular formula $C_4H_8O_2$ that contain more than one functional group.

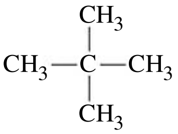
30. Give the isomers with molecular formula $C_5H_{10}O_2$ that contain more than one functional group.

Nomenclature and Formulas

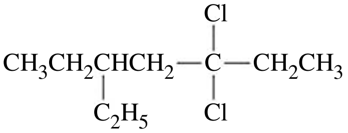
31. Give an acceptable name for each of the following.

(a)


$\mathrm{CH_3CH_2CH_2\overset{CH_3}{\overset{|}{C}}HCH_2\overset{CH_3}{\overset{|}{C}}HCH_2CH_3}$

(b)


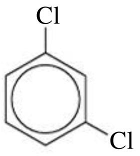
$\mathrm{CH_3-\overset{CH_3}{\underset{CH_3}{C}}-CH_3}$

(c)


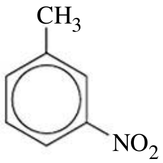
$\mathrm{CH_3CH_2\underset{C_2H_5}{C}HCH_2-\overset{Cl}{\underset{Cl}{C}}-CH_2CH_3}$

32. Give an acceptable name for each of the following.

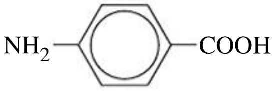
(a)



(b)



(c)

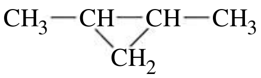


33. Give an acceptable name for each of the following structures.

(a) $CH_3CH_2C(CH_3)_3$

(b) $(CH_3)_2C{=}CH_2$

(c)



(d) $CH_3C{\equiv}CCH(CH_3)_2$

(e) $CH_3CH(C_2H_5)CH(CH_3)CH_2CH_3$

(f) $CH_3CH(CH_3)CH(CH_3)CCH_2CH_2CH_3{=}CH_2$

34. Draw a condensed structure to correspond to each of the following names.
(a) methylbutane; **(b)** cyclohexene;
(c) 2-methyl-3-hexyne; **(d)** 2-butanol;
(e) ethyl isopropyl ether; **(f)** propanal

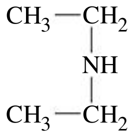
35. Does each of the following names convey sufficient information to suggest a specific structure? Explain.
(a) pentene; **(b)** butanone; **(c)** butyl alcohol;
(d) methylaniline; **(e)** methylcyclopentane;
(f) dibromobenzene

36. Indicate why each of these names is incorrect, and give a correct name.
(a) 3-pentene; **(b)** pentadiene; **(c)** 1-propanone;
(d) bromopropane; **(e)** 2,6-dichlorobenzene;
(f) 2-methyl-3-pentyne

37. Supply condensed structural formulas for the following substances.
(a) 2,4,6-trinitrotoluene (TNT—an explosive)
(b) methyl salicylate (oil of wintergreen) [*Hint:* Salicylic acid is *o*-hydroxybenzoic acid.]
(c) 2-hydroxy-1,2,3-propanetricarboxylic acid (citric acid, $C_6H_8O_7$)

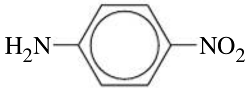
38. Supply condensed structural formulas for the following substances.
(a) *o-tert*-butylphenol (an antioxidant in aviation gasoline)
(b) 1-phenyl-2-aminopropane (benzedrine—an amphetamine, ingredient in "pep pills")
(c) 2-methylheptadecane (a sex pheromone of tiger moths—a chemical used for communication among members of the species) [*Hint:* Heptadeca means 17.]

39. Name the following amines.

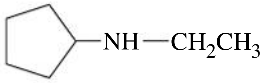
(a)


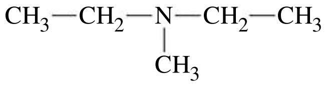
$$\begin{array}{rc}\mathrm{CH_3-} & \mathrm{CH_2} \\ & | \\ & \mathrm{NH} \\ & | \\ \mathrm{CH_3-} & \mathrm{CH_2}\end{array}$$

(b)



(c)



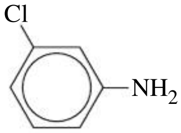
(d)


$\mathrm{CH_3-CH_2-\underset{CH_3}{\underset{|}{N}}-CH_2-CH_3}$

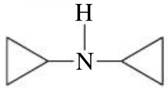
40. Name the following amines.

(a) $CH_3{-}CH_2{-}NH_2$

(b)



(c)



(d) $Cl{-}CH_2{-}CH_2{-}NH_2$

Alkanes and Cycloalkanes

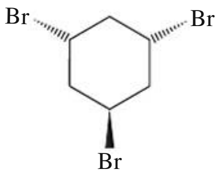
41. Classify the carbon atoms in **(a)** methylbutane, and **(b)** 2,2-dimethylpropane as methyl, primary (1°), secondary (2°), tertiary (3°), or quaternary (4°).

42. Classify the carbon atoms in **(a)** 2,4-dimethylpentane, and **(b)** ethylcyclobutane as methyl, primary (1°), secondary (2°), tertiary (3°), or quaternary (4°).

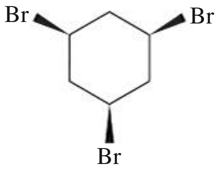
43. Draw Newman projections for the staggered and eclipsed conformations of pentane for rotation about the C2—C3 bond. Which conformation is lowest in energy?

44. Draw Newman projections for the staggered and eclipsed conformations of 2-methylpentane for rotation about the C2—C3 bond. Which conformation is lowest in energy?

45. Draw the most stable conformation for the molecule below:



46. Draw the most stable conformation for the molecule below:



47. For each of the following substituted cyclohexanes, draw the two possible chair conformations, label each substituent as axial or equatorial, and identify the more stable conformer.

(a) cyclohexanol

(b) *trans*-3-methylcyclohexanol

48. For each of the following substituted cyclohexanes, draw the two possible chair conformations, label each substituent as axial or equatorial, and identify the more stable conformer.

(a) *cis*-1-isopropyl-3-methylcyclohexane

(b) *cis*-4-*tert*-butylcyclohexanol

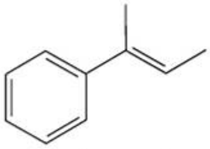
Alkenes

49. Why is it not necessary to refer to ethene and propene as 1-ethene and 1-propene? Can the same be said for butene?

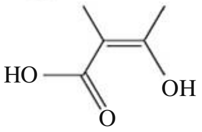
50. Alkenes (olefins) and cyclic alkanes (alicyclics) each have the generic formula C_nH_{2n}. In what important ways do these types of compounds differ structurally?

51. Assign a configuration (*E* or *Z*) to each of the following molecules.

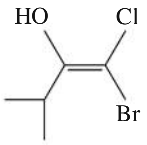
(a)



(b)

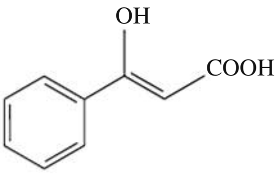


(c)

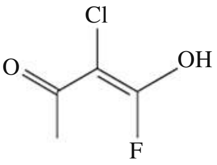


52. Assign a configuration (*E* or *Z*) to each of the following molecules.

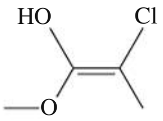
(a)



(b)



(c)



53. Draw the *E* and *Z* isomers of **(a)** 2-chloro-2-butene; **(b)** 3-methyl-2-pentene

54. Draw the *E* and *Z* isomers of **(a)** 3-methyl-3-hexene; **(b)** 3-fluoro-2-methyl-3-hexene

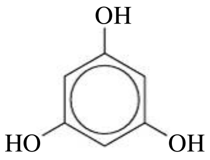
Aromatic Compounds

55. Supply a name or structural formula for each of the following.

(a) phenylacetylene

(b) *m*-dichlorobenzene

(c)

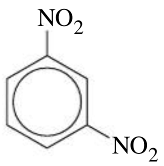


56. Supply a name or structural formula for each of the following.

(a) *p*-phenylphenol

(b) 3-hydroxy-4-isopropyltoluene (thymol—flavor constituent of the herb thyme)

(c)



Organic Stereochemistry

57. Draw suitable structural formulas to show that there are *four* constitutional isomers of $C_3H_6Cl_2$.

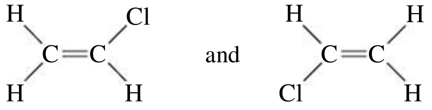
58. Which of the following pairs of molecules are constitutional isomers and which are not? Explain.

(a) $CH_3CH_2CH_2CH_3$ and $CH_3CH{=}CHCH_3$

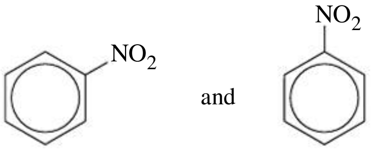
(b) $CH_3(CH_2)_5CH(CH_3)_2$ and $CH_3(CH_2)_4CH(CH_3)CH_2CH_3$

(c) $CH_3CHClCH_2CH_3$ and $CH_3CH_2CH_2CH_2CH_2Cl$

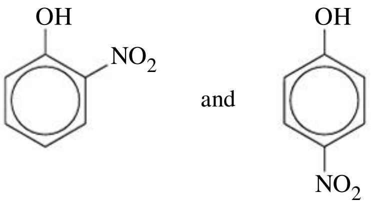
(d)



(e)

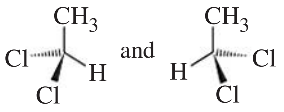


(f)

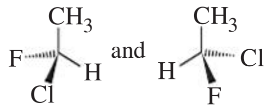


59. For each pair of structures shown below, indicate whether the two species are identical molecules, enantiomers, or isomers of some other sort.

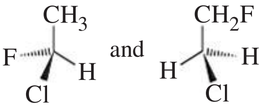
(a)



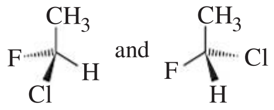
(b)



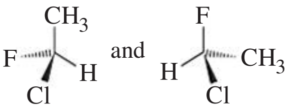
(c)



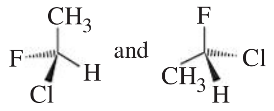
(d)



(e)

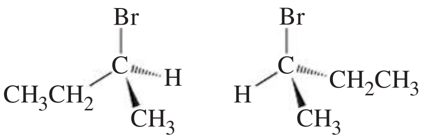


(f)

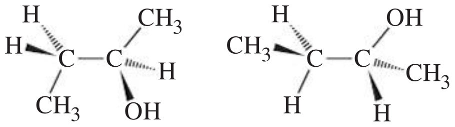


60. For each pair of structures shown below, indicate whether the two species are identical molecules, enantiomers, or isomers of some other sort.

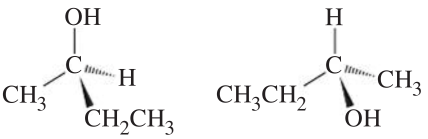
(a)



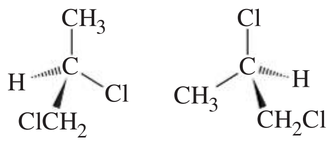
(b)



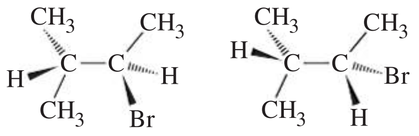
(c)



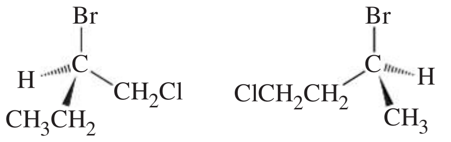
(d)



(e)

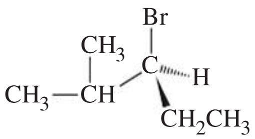


(f)

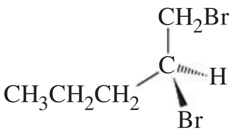


61. Name the following molecules with the appropriate stereochemical designation.

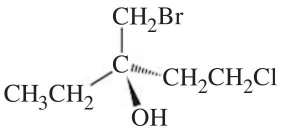
(a)



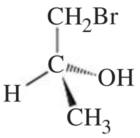
(b)



(c)

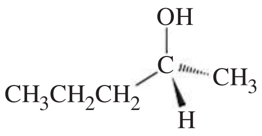


(d)

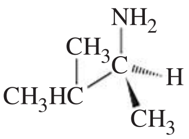


62. Name the following molecules with the appropriate stereochemical designation.

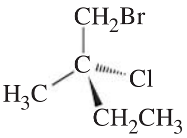
(a)



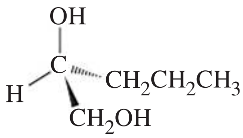
(b)



(c)



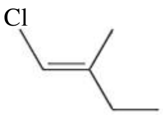
(d)



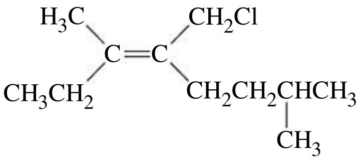
63. Name the following molecules with the appropriate stereochemical designation.

(a)

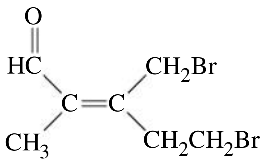
(b)



(c)

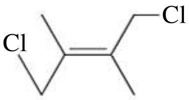


(d)

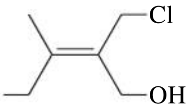


64. Name the following molecules with the appropriate stereochemical designation.

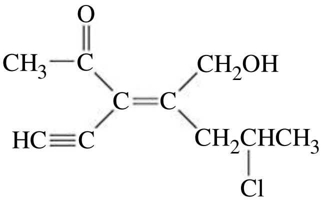
(a)



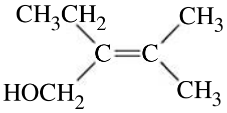
(b)



(c)



(d)



65. Draw the structure for each of the following.
- **(a)** (*Z*)-1,3,5-tribromo-2-pentene
- **(b)** (*E*)-1,2-dibromo-3-methyl-2-hexene
- **(c)** (*S*)-1-bromo-1-chlorobutane
- **(d)** (*R*)-1,3-dibromohexane
- **(e)** (*S*)-1-chloro-2-propanol

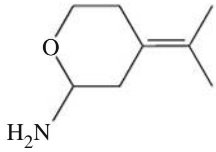
66. Draw the structure for each of the following.
- **(a)** (*R*)-1-bromo-1-chloroethane
- **(b)** (*E*)-2-bromo-2-pentene
- **(c)** (*Z*)-1-chloro-3-ethyl-3-heptene
- **(d)** (*R*)-2-hydroxypropanoic acid
- **(e)** (*S*)-2-aminopropanoate anion

Structures and Properties of Organic Compounds

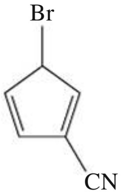
67. Consider the following molecular formulas. How many elements of unsaturation are there in each case? **(a)** $C_4H_{11}N$; **(b)** C_4H_6O; **(c)** $C_9H_{15}ClO$.

68. Consider the following molecular formulas. How many elements of unsaturation are there in each case? **(a)** C_5H_9NO **(b)** $C_5H_8O_3$; **(c)** C_5H_9ClO.

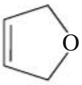
69. How many elements of unsaturation are there in the molecule below? What is the molecular formula?



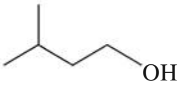
70. How many elements of unsaturation are there in the molecule below? What is the molecular formula?



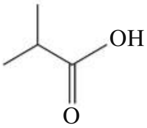
71. Match the following compounds with the chemical properties given below. Write a chemical equation for the reactions described in (a)–(d).



(1)



(2)

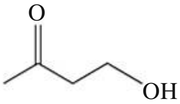


(3)

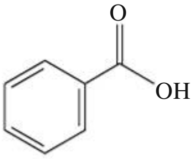
- **(a)** is easily oxidized
- **(b)** decolorizes bromine water
- **(c)** generates bubbles of gas when treated with $Na_2CO_3(aq)$
- **(d)** generates bubbles of gas when sodium metal is added

72. Match the following compounds with the chemical properties given below. Write a chemical equation for the reactions described in (a)–(d).

(1)



(2)



(3)

- **(a)** forms an ester with ethanol
- **(b)** absorbs H_2 in the presence of a metal catalyst
- **(c)** neutralizes dilute NaOH
- **(d)** forms an ether when heated strongly with H_2SO_4

73. Draw as many structural isomers as you can for cyclic ethers (no —OH groups) having the formula C_4H_6O. Try to draw at least six. (There are more than six.)

74. Draw as many structural isomers as you can for cyclic alcohols having the formula C_4H_6O. Try to draw at least five. (There are more than five.)

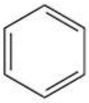
Integrative and Advanced Exercises

75. Supply condensed or structural formulas for the following substances.
(a) 1,5-cyclooctadiene (an intermediate in the manufacture of resins)
(b) 3,7,11-trimethyl-2,6,10-dodecatriene-1-ol (farnesol—odor of lily of the valley) [*Hint:* Dodeca means 12.]
(c) 2,6-dimethyl-5-hepten-1-al (used in the manufacture of perfume)

76. Draw structural formulas for all the isomers listed in Table 26.3, and show that, indeed, the substances with more compact structures have lower boiling points.

77. By drawing suitable structural formulas, establish that there are *17* isomers of $C_6H_{13}Cl$. [*Hint:* Refer to Example 26-1.]

78. The symbol:



is often used to represent benzene. It is also the structural formula of cyclohexatriene. Are benzene and cyclohexatriene the same substance? Explain.

79. Use the half-reaction method to balance the following redox equations.
(a) $C_6H_5NO_2 + Fe + H^+ \longrightarrow C_6H_5NH_3^+ + Fe^{3+} + H_2O$
(b) $C_6H_5CH_2OH + Cr_2O_7^{2-} + H^+ \longrightarrow C_6H_5CO_2H + Cr^{3+} + H_2O$
(c) $CH_3CH{=}CH_2 + MnO_4^- + H_2O \longrightarrow CH_3CHOHCH_2OH + MnO_2 + OH^-$

80. A 10.6 g sample of benzaldehyde was allowed to react with 5.9 g $KMnO_4$ in an excess of KOH(aq). After filtration of the $MnO_2(s)$ and acidification of the solution, 6.1 g of benzoic acid was isolated. What was the percent yield of the reaction? [*Hint:* Write half-equations for the oxidation and reduction half-reactions.]

81. Combustion of a 0.1908 g sample of a compound gave 0.2895 g CO_2 and 0.1192 g H_2O. Combustion of a second sample weighing 0.1825 g yielded 40.2 mL of $N_2(g)$, collected over 50% KOH(aq) (vapor pressure = 9 mmHg) at 25 °C and 735 mmHg barometric pressure. When 1.082 g of compound was dissolved in 26.00 g benzene (mp 5.50 °C, $K_f = 5.12\ °C\ m^{-1}$), the solution had a freezing point of 3.66 °C. What is the molecular formula of this compound?

82. Draw and name all derivatives of benzene having the formula **(a)** C_8H_{10}; **(b)** C_9H_{12}.

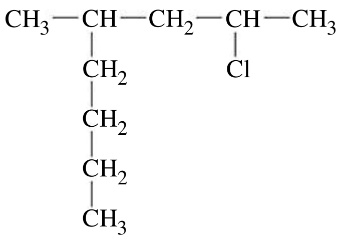
83. In the monochlorination of hydrocarbons, a hydrogen atom is replaced by a chlorine atom. How many different monochloro derivatives of 2-methylbutane are possible?

84. A particular colorless organic liquid is known to be one of the following compounds: 1-butanol, diethyl ether, methyl propyl ether, butyraldehyde, or propionic acid. Can you identify which it is, based on the following tests? If not, what additional test would you perform? (1) A 2.50 g sample dissolved in 100.0 g water has a freezing point of −0.7 °C. (2) An aqueous solution of the liquid does not change the color of blue litmus paper. (3) When alkaline $KMnO_4(aq)$ is added to the liquid and the mixture is heated, the purple color of the MnO_4^- disappears.

85. Write structural formulas for the following.
(a) 2,4-dimethyl-1,4-pentadiene
(b) 2,3-dimethylpentane
(c) 1,2,4-tribromobenzene
(d) methylethanoate
(e) butanone

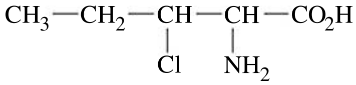
86. Give the systematic names, including any stereochemical designations, for each of the following.

(a)



$CH_3-\underset{\substack{|\\CH_2\\|\\CH_2\\|\\CH_2\\|\\CH_3}}{CH}-CH_2-\underset{\substack{|\\Cl}}{CH}-CH_3$

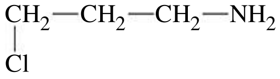
(b)



$CH_3-CH_2-\underset{\substack{|\\Cl}}{CH}-\underset{\substack{|\\NH_2}}{CH}-CO_2H$

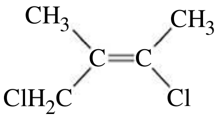
(c) $CH_3OCH_2CH_3$

(d)



$\underset{\substack{|\\Cl}}{CH_2}-CH_2-CH_2-NH_2$

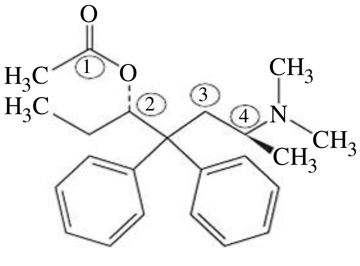
(e)



87. Write structural formulas for all the isomers of C_4H_7Cl. Indicate any enantiomers or diastereomers that occur.

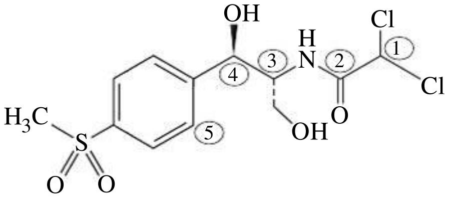
88. Compound A is an alcohol of formula $C_5H_{12}O$ that can be resolved into enantiomers.
(a) Draw *three* possible structures of compound A.
(b) Treatment of A with CrO_3/pyridine gives compound B, which also exhibits optical activity. What are the structural formulas of A and of B? Name and draw the enantiomers of A and B.

89. Levomethadyl acetate (shown below) is used in the treatment of narcotic addiction.



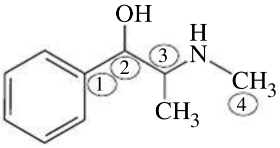
(a) Name the functional groups in levomethadyl acetate. **(b)** What is the hybridization of the numbered carbon atoms and the nitrogen atom? **(c)** Which, if any, of the numbered carbon atoms are chiral?

90. Thiamphenicol (shown below) is an antibacterial agent.



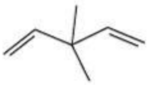
(a) Name the functional groups of thiamphenicol.
(b) What is the hybridization of the numbered carbon atoms and the nitrogen atom?
(c) Which, if any, of the numbered carbon atoms are chiral?

91. Ephedrine (shown below) is used as a decongestant in cold remedies.

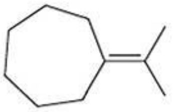


(a) Name the functional groups of ephedrine. **(b)** What is the hybridization of the numbered carbon atoms and the nitrogen atom? **(c)** Which, if any, of the numbered carbon atoms are chiral? **(d)** The pH of a solution of 1 g of ephedrine in 200 g of water is 10.8. What is the pK_b of ephedrine?

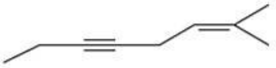
92. For each of the following molecules, determine the hybridization of each carbon atom, the total number of σ bonds and the total number of π bonds. Also, among the sp^3-hybridized carbon atoms, which ones are primary (1°), secondary (2°), tertiary (3°), or quaternary (4°)?



(a)



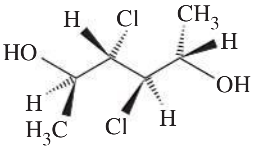
(b)



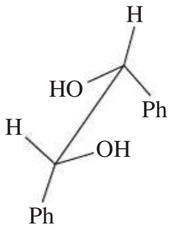
(c)

93. Determine the configuration, *R* or *S*, of each chiral carbon atom in the molecules below. (Ph represents a phenyl group.)

(a)

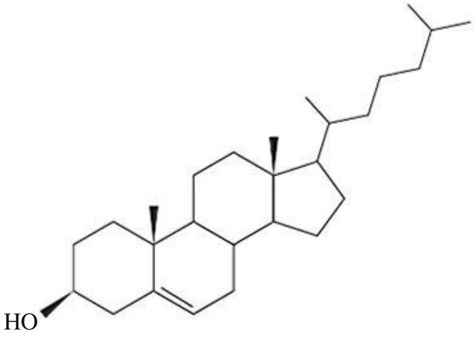


(b)



94. Among all ethers with the formula C_4H_6O, draw structures for
(a) two ethers with two sp^2 and two sp^3 carbon atoms
(b) an ether with four sp^2 carbon atoms
(c) an ether with two sp and two sp^3 carbon atoms

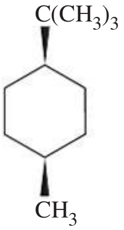
95. A structural formula for cholesterol is shown below. How many chiral carbon atoms are there in the cholesterol molecule? What is the configuration, *R* or *S*, of the carbon atom bonded to the —OH group? What is the configuration, *E* or *Z*, of the double bond?



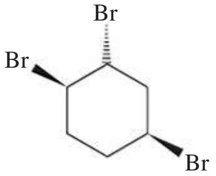
Cholesterol

96. For each of the following molecules **(a)** draw the two chair conformations and specify which conformation is more stable; **(b)** determine the number of chiral carbon atoms and for each chiral carbon, determine its configuration (*R* or *S*).

(1)



(2)



Feature Problem

97. Organic chemists use a variety of methods to help them identify the functional groups in a molecule. In this chapter, we mentioned a few simple chemical ways to test for alkenes, alcohols, carboxylic acids, and so on. Such tests are quick and easy, but today organic chemists rely heavily on instrumental techniques. *Infrared (IR) spectroscopy* is an instrumental technique for identifying functional groups in a molecule. When infrared radiation is absorbed by a molecule, it causes atoms in bonds to vibrate back and forth with increased amplitude. We saw (in Chapter 8) that the energies of electrons in atoms are quantized and so too are the vibrations of atoms in molecules. Because each functional group has a particular grouping of atoms, there is a characteristic infrared absorption associated with each type of functional group. Some characteristic infrared absorptions are summarized in the following table. Infrared absorptions of molecules are identified by specifying the *wavenumber* of the light that is absorbed. The wavenumber is simply the reciprocal of wavelength: wavenumber $= 1/\lambda = v/c$. (The definitions of λ, v, and c were given in Chapter 8.) The SI unit for wavenumber is m^{-1} but it is often given in units of cm^{-1}. The wavenumber represents the number of cycles of the wave in each meter or centimeter along the light beam.

The data in the table indicate that molecules containing the carbonyl group (C═O) absorb light with wavenumbers between 1680 and 1750 cm^{-1}. Molecules containing a carbon–carbon triple bond (C≡C) absorb light with wavenumbers between 2100 and 2200 cm^{-1}. To identify the functional groups present in a molecule, the *infrared spectrum* of the molecule is obtained by using an instrument called an *infrared spectrometer*. A schematic diagram of an infrared spectrometer is shown below.

The light from the infrared light source is directed through a monochromator, which can be set to select a specific wavelength of light. The light then passes through a beam splitter, which splits the light into two separate beams, a reference beam and an incident beam. If the wavenumber of the incident beam matches one of the characteristic absorptions of the molecule, the sample absorbs the light, producing molecules that vibrate with greater energy. Because light has been absorbed by the sample, the intensity of the transmitted beam is less than that of the reference beam. The decrease in intensity is detected by the detector. By varying the wavenumber of light that reaches the sample and monitoring the percentage of light that is transmitted, an infrared spectrum is obtained (see graphs). An infrared spectrum is a plot of percent transmittance versus wavenumber. One hundred percent transmittance means none of the incident light was absorbed and 0% transmittance means all of the incident light was absorbed.

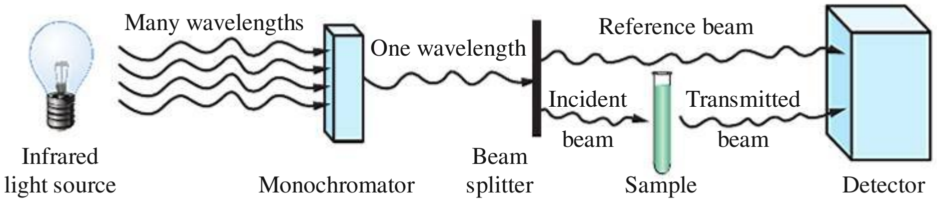
Type of bond	Wavenumber, cm^{-1}
Single bonds	
—C—H	2850–3300
═C—H	3000–3100
≡C—H	≈3300
N—H	3300–3500
O—H	3200–3600
Double bonds	
C═C	1620–1680
C═N	1500–1650
C═O	1680–1750
Triple bonds	
C≡C	2100–2200
C≡N	2200–2300

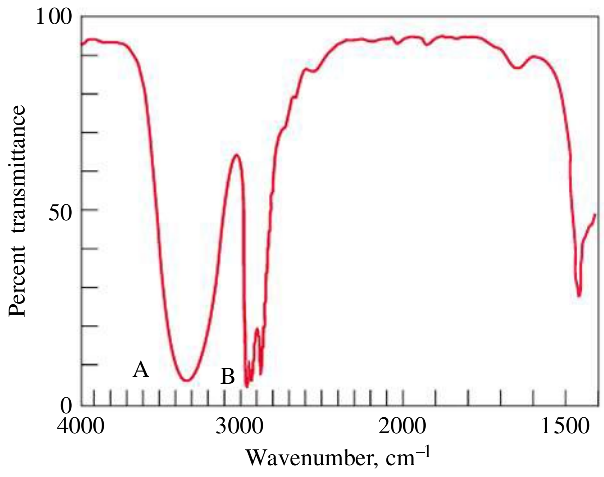
(a) The infrared absorptions given in the table above range from 1500 cm^{-1}. to 3600 cm^{-1}. Calculate the corresponding ranges of wavelength and frequency to verify that these absorptions correspond to the infrared region of the electromagnetic spectrum. (See Figure 8.3.)

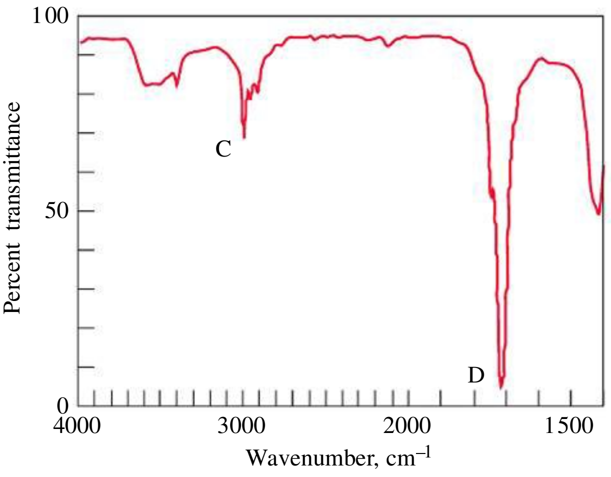
(b) Identify the bonds responsible for the absorptions labeled A, B, C, and D in the two infrared spectra shown here. One spectrum is for acetone and the other is for 1-propanol, both of which are colorless liquids. Which of the two spectra is that of acetone?

(c) An isomer of acetone exhibits a strong IR absorption at 1645 cm^{-1} and also absorbs strongly from 2860 through 3600 cm^{-1}. The compound decolorizes bromine water, $Br_2(aq)$, and produces bubbles of gas when sodium metal is added to it. What is the structure of this compound?

Infrared spectrometer

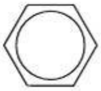






Self-Assessment Exercises

98. In your own words, define the following terms or symbols:
(a) *tert*-
(b) R—
(c)



(d) carbonyl group
(e) primary amine

99. Explain the important distinctions between each pair of terms: **(a)** alkane and alkene; **(b)** aliphatic and aromatic compound; **(c)** alcohol and phenol; **(d)** ether and ester; **(e)** amine and ammonia.

100. Describe the characteristics of each of the following types of isomers: **(a)** constitutional; **(b)** stereoisomer **(c)** cis; **(d)** ortho.

101. The compound isoheptane is best represented by the formula **(a)** C_7H_{14}; **(b)** $CH_3(CH_2)_5CH_3$; **(c)** $(CH_3)_2CH(CH_2)_3CH_3$; **(d)** $C_6H_{11}CH_3$.

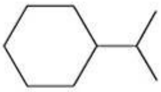
102. A compound with the same hydrogen-to-carbon ratio as cyclobutane is **(a)** C_4H_{10}; **(b)** $CH_3CH{=}CHCH_3$; **(c)** $CH_3C \equiv CCH_3$; **(d)** C_6H_6.

103. Three isomers exist of the hydrocarbon **(a)** C_3H_8; **(b)** C_4H_8; **(c)** C_4H_{10}; **(d)** C_6H_6; **(e)** C_5H_{12}.

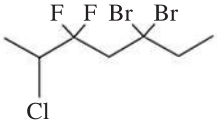
104. Give names for the following molecules.

(a) $(CH_3)_2CBrCH_2CHClCH_2CH(CH_3)_2$

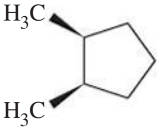
(b)



(c)



105. Assign configurations, *R* or *S*, to the chiral carbons in the molecules below. Then identify **(a)** any two identical structures; **(b)** any two constitutional isomers; **(c)** any two diastereomers; **(d)** a pair of enantiomers.



(1)

A branch of the Pacific Yew tree (*Taxus brevifolia*), which grows in forests along the Pacific coast of British Columbia and Washington. The needles and seeds of the Pacific Yew are poisonous but the bark contains a compound called paclitaxel (formerly known as taxol), an effective chemotherapy drug. Unfortunately, the bark of a 100-year-old Pacific yew tree yields about 3 kilograms of bark and only 300 mg of paclitaxel—barely enough for a single dose. Paclitaxel is a complicated organic molecule, the structure of which was determined in 1971. In 1994, two different groups of organic chemists, one lead by Professor Robert A. Holton of Florida State University and another lead by Professor Kyriacos C. Nicolau of the University of California (San Diego), announced independently that they were able to synthesize paclitaxel from simple starting materials.

In Chapter 26, we focused primarily on the structures of organic compounds and learned that organic compounds can be categorized into a relatively small number of families: alkanes, haloalkanes, alcohols, alkenes, and so on. In this chapter, we are interested in the characteristic reactions of some of these compounds and the mechanisms that describe how these reactions occur. Given that millions of organic compounds are known, and countless reactions involving them are possible, it may seem surprising that the reactions of organic compounds can be rationalized in terms of a relatively small number of reaction mechanisms. In this chapter, we will explore a few of these mechanisms.

We cannot possibly provide a complete perspective of organic reactions and their mechanisms in one chapter. We will focus instead on core concepts that will not only help us understand the reactions but also serve us well in more advanced organic chemistry courses. Throughout this chapter, we will emphasize the molecular aspects of chemical reactions—molecules coming together, with electron-rich regions being drawn naturally toward electron-poor regions; old bonds breaking and new bonds forming. We will use ideas about the structures and properties of molecules—gained in earlier chapters—to help us understand some important ideas about reactions of organic compounds.

We begin with a brief overview of the different types of organic reactions and then discuss these reaction types in terms of the structures of the molecules involved, the acidic or basic character of the reacting species, and the relative stabilities of reactants, products, and reaction intermediates. We will rely heavily on concepts from earlier chapters but will apply them in new ways. Also, we will make much more use of line-angle structures in this chapter to emphasize the functional groups and the prominent role they play in organic reactions.

27-1 Organic Reactions: An Introduction

Organic compounds undergo a variety of different reactions, including substitution, addition, elimination, and rearrangement reactions. In a **substitution reaction**, an atom, an ion, or a group in one molecule is replaced by (substituted with) another. Here are a few examples of substitution reactions:

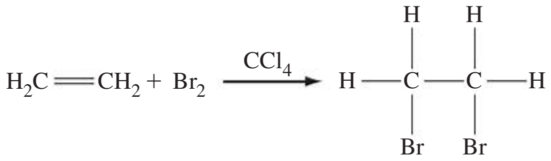
$$\mathrm{CH_3Cl + NaOH \xrightarrow{H_2O} CH_3OH + NaCl}$$

$$\mathrm{(CH_3)_3CBr + H_2O \xrightarrow[\Delta]{(CH_3)_2CO} (CH_3)_3COH + HBr}$$

$$\mathrm{C_6H_6 + HNO_3 \xrightarrow{H_2SO_4} C_6H_5NO_2 + H_2O}$$

In each equation, the solvent used in the reaction is written above the arrow. In the first reaction, the Cl atom in a CH_3Cl molecule is substituted with an —OH group. In the second reaction, the Br atom in a $(CH_3)_3CBr$ molecule is substituted with an —OH group, and in the third reaction, an H atom in a C_6H_6 molecule is substituted with an $—NO_2$ group. Although each reaction is a substitution reaction, we will soon see that they occur via different mechanisms.

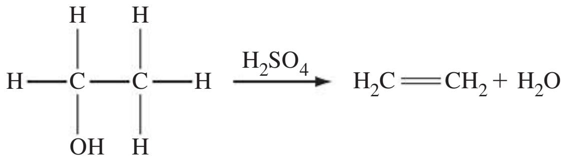
In an **addition reaction**, a molecule adds across a double or triple bond in another molecule. Here are two examples:



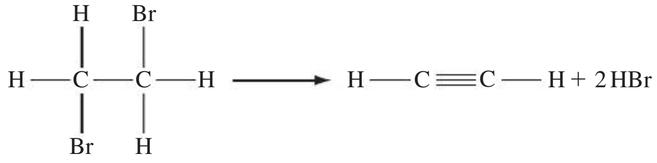
$$\mathrm{H_2C{=}CH_2 + Br_2 \xrightarrow{CCl_4} H-\overset{H}{\underset{Br}{C}}-\overset{H}{\underset{Br}{C}}-H}$$

$$\mathrm{HC{\equiv}CH + HBr \longrightarrow H_2C{=}CHBr}$$

In an **elimination reaction**, atoms or groups that are bonded to adjacent atoms are eliminated as a small molecule. Typically, the order of the bond between the two adjacent atoms increases as a result of the elimination, as shown in the examples below:



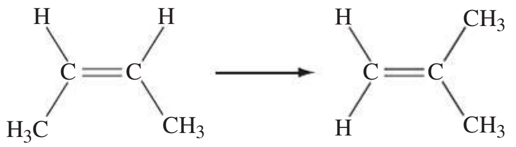
$$\mathrm{H-\overset{H}{\underset{OH}{C}}-\overset{H}{\underset{H}{C}}-H \xrightarrow{H_2SO_4} H_2C{=}CH_2 + H_2O}$$

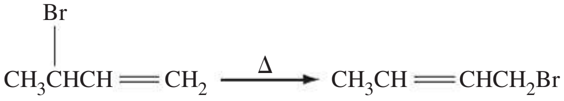


$$\mathrm{H-\overset{H}{\underset{Br}{C}}-\overset{Br}{\underset{H}{C}}-H \longrightarrow H-C{\equiv}C-H + 2HBr}$$

The first of the two reactions above illustrates that alkenes can be obtained from alcohols (ROH). The second, in which two molecules of HBr are eliminated to yield an alkyne, is an example of a double elimination reaction.

When an organic compound undergoes a **rearrangement reaction** (or an isomerization reaction), the carbon skeleton of a molecule is rearranged.



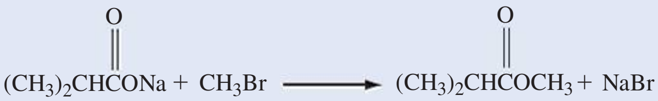


$$CH_3\overset{Br}{\overset{|}{C}}HCH{=}CH_2 \xrightarrow{\Delta} CH_3CH{=}CHCH_2Br$$

EXAMPLE 27-1 Identifying Types of Organic Reactions

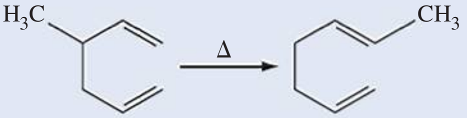
State whether each of the following reactions is a substitution, an addition, an elimination, or a rearrangement reaction. (In the equations below, H^+ and Pb are catalysts.)

(a)



$$(CH_3)_2CH\overset{O}{\overset{\|}{C}}ONa + CH_3Br \longrightarrow (CH_3)_2CH\overset{O}{\overset{\|}{C}}OCH_3 + NaBr$$

(b)



(c) $2\,CH_3OH \xrightarrow[\Delta]{H^+} CH_3OCH_3 + H_2O$

(d) cyclohexanol $\xrightarrow[\Delta]{H^+}$ cyclohexene + water

(e) 2-butyne + 2 H_2 $\xrightarrow{Pb}$ butane

Analyze

In a substitution reaction, an atom or a group of atoms is replaced with another atom or group of atoms. In an addition reaction, atoms add across a double or triple bond, causing a reduction in bond order between two atoms. In an elimination reaction, atoms or groups of atoms that are bonded to adjacent atoms are eliminated, causing an increase in bond order between two atoms. Typically, a rearrangement reaction involves a change in constitution or stereochemical configuration.

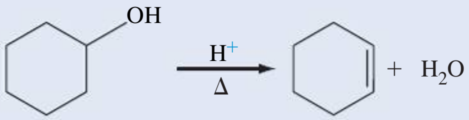
Solve

(a) Because a Br atom in CH_3Br is replaced by a $(CH_3)_2CHCOO$ group, the reaction is a substitution reaction.

(b) The reaction involves only a change in the skeletal structure (constitution), and so the reaction is a rearrangement reaction.

(c) When we write the reaction out as $CH_3OH + CH_3OH \longrightarrow CH_3OCH_3 + H_2O$, we see that an —OH group in one molecule is replaced by a $—CH_3O$ group. The reaction is a substitution reaction.

(d) Here, we need to convert the names of the compounds into structural formulas.



The reaction involves elimination of OH and H from adjacent carbon atoms in cyclohexanol. Thus, the reaction is an elimination reaction.

(e) In this reaction, an alkyne is converted into an alkane. Because there is a reduction in bond order, we know that the reaction is an addition reaction involving the addition of H atoms across the triple bond. Our prediction is confirmed by writing the reaction in terms of structural formulas:

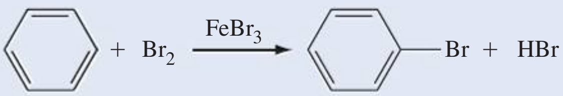
$$CH_3C{\equiv}CCH_3 + 2\,H_2 \longrightarrow CH_3CH_2CH_2CH_3$$

Assess

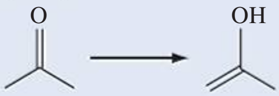
To identify the reaction type correctly, it is often helpful to write out structural formulas for all molecules involved.

PRACTICE EXAMPLE A: Classify the following reactions as substitution, addition, elimination, or rearrangement reactions.

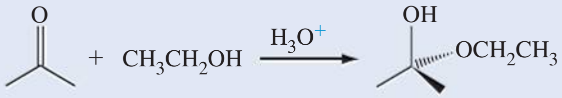
(a)



(b)



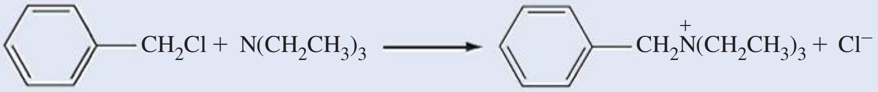
(c)



PRACTICE EXAMPLE B: Classify each of the following reactions as a substitution, an addition, an elimination, or a rearrangement reaction.

(a) $CH_3CH_2CH_2CH_2Br + (CH_3)_3O^-K^+ \longrightarrow CH_3CH_2CH{=}CH_2 + KBr + (CH_3)_3OH$

(b)



CH_2Cl + $N(CH_2CH_3)_3$
$CH_2\overset{+}{N}(CH_2CH_3)_3$ + Cl^-

(c) $CH_3CH_2C{\equiv}C^-Na^+ + CH_3CH_2Br \longrightarrow CH_3CH_2C{\equiv}CCH_2CH_3 + NaBr$

27-2 Introduction to Nucleophilic Substitution Reactions

In this section, we consider the essential features of substitution reactions involving compounds in which the functional group is bonded to an sp^3-hybridized carbon atom. We will focus primarily on substitution reactions of haloalkanes. In a haloalkane, the carbon atom bonded to the halogen is sp^3 hybridized. With appropriate modifications, the concepts learned in this section can be used to understand substitution reactions of other compounds.

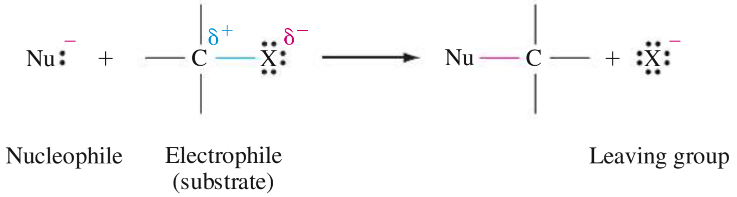
An example of a substitution reaction involving an sp^3 hybridized carbon is the replacement of a Cl atom in chloromethane by a hydroxide group to give methanol:

$$CH_3Cl + OH^- \longrightarrow CH_3OH + Cl^- \qquad \textbf{(27.1)}$$

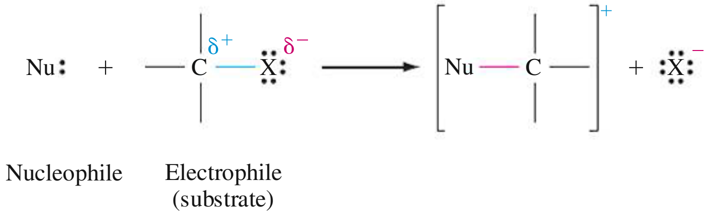
▲ Volcanic eruptions produce significant quantities of chloromethane, CH_3Cl.

This type of chemical reaction is called a **nucleophilic substitution reaction** because the hydroxide ion is a **nucleophile**—a reactant that seeks sites of low electron density in a molecule. The nucleophile is electron rich, and it is the species that donates a pair of electrons to another molecule. The C atom in CH_3Cl is considered electron deficient because, as discussed in Chapter 11, the Cl atom draws electron density away from the C atom; the C atom is said to be electrophilic (electron attracting). The **electrophile**, also known as the **substrate**, is the species that is being attacked by the nucleophile and accepts a pair of electrons. Electrophiles contain atoms that are electron deficient. In reaction (27.1), the hydroxide ion attacks at the electron deficient C atom, displacing the chloride ion, which is called the **leaving group**.

Nucleophiles, often denoted by the abbreviation Nu, can be negatively charged or neutral, but every nucleophile contains at least one pair of unshared electrons. Nucleophiles are, in fact, Lewis bases. The nucleophilic substitution of a haloalkane is described by either of two general equations:



(27.2a)

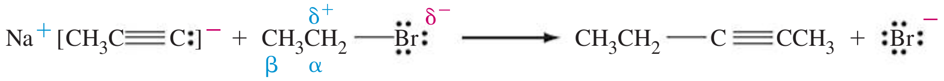


(27.2b)

In a nucleophilic substitution reaction, the bond (in blue) between carbon and the leaving group is broken and a new bond (in red) is formed by using a lone pair from the nucleophile. The electron pair from the bond that is broken ends up as a lone pair on the leaving group. In light of the discussion of acid–base chemistry in Section 27A on www.masteringchemistry.com, equilibrium favors forming the substitution product if the leaving group is a weaker base than the nucleophile.

As we will soon see, nucleophilic substitution of haloalkanes occurs via one of two mechanisms. Before examining the mechanisms, let's consider a few specific examples of nucleophilic substitution reactions.

In the reaction below, the $CH_3C{\equiv}C^-$ ion is the nucleophile and CH_3CH_2Br is the electrophile:



$$Na^+[CH_3C{\equiv}C\!:]^- + \underset{\beta\ \ \alpha}{\overset{\delta+}{CH_3CH_2}}{-}\overset{\delta-}{\ddot{B}r\!:} \longrightarrow CH_3CH_2{-}C{\equiv}CCH_3 + :\ddot{B}r:^-$$

▶ In a haloalkane, the carbon bonded to the halogen atom is called the alpha (α) carbon. A carbon bonded to the α carbon is called a beta (β) carbon. A carbon bonded to a β carbon is called a gamma (γ) carbon, and so on. This system of labeling carbon atoms is important when discussing reactions.

The α carbon is electron deficient (d+); it is the atom of the electrophile that is attacked by the nucleophile. Because both the nucleophile and the leaving group are Lewis bases, we can use acid–base concepts to establish that the reaction above will occur as written. The $CH_3C{\equiv}C^-$ ion has the negative charge localized on C, a very small atom compared with Br, and so the $CH_3C{\equiv}C^-$ is a much stronger base than Br^-. Because the reaction involves the formation of a weaker base, the reaction will occur as written.

In contrast to the example above, the following substitution reactions will not occur as written because they both involve the formation of a base that is stronger than the nucleophile:

$$HO^- + H_3C{-}H \not\longrightarrow H_3C{-}OH + H^- \text{ (}H^-\text{ is a stronger base than }OH^-\text{)}$$

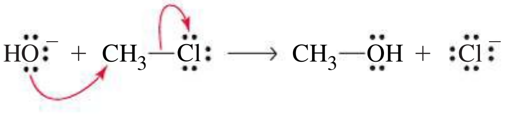
$$Br^- + CH_3CH_2{-}OH \not\longrightarrow CH_3CH_2{-}Br + OH^- \text{ (}OH^-\text{ is a stronger base than }Br^-\text{)}$$

The S_N1 and S_N2 Mechanisms of Nucleophilic Substitution Reactions

Chemical research, starting in the 1890s, has shown that nucleophilic substitution reactions can involve two types of mechanisms. The reaction between chloromethane and the hydroxide ion (27.2) has a rate law that is first order in both the nucleophile and the electrophile. That is,

$$\text{rate} = k[OH^-][CH_3Cl]$$

The mechanism for this reaction involves a bimolecular rate-determining step in which the nucleophilic group approaches the electrophilic carbon atom and, simultaneously, the leaving group departs. The entering and leaving groups act at the same time in what is known as a *concerted step*, as depicted in this schematic representation:



$$HO^- + CH_3{-}Cl \longrightarrow CH_3{-}OH + Cl^-$$

▲ Sir Robert Robinson (1886–1975) was awarded the 1947 Nobel Prize in Chemistry for his contributions to the synthesis of natural products. He is also credited with introducing the use of curved arrows to show the movement of electron pairs in chemical reactions.

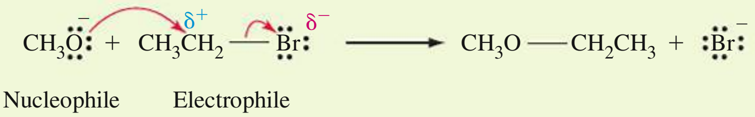
Acid–base concepts are among the most important of all concepts in chemistry because all chemical reactions—including those involving organic molecules—can be characterized as some form of acid–base reaction. For a discussion of acid–base concepts, with a focus on organic reactions, see Section 27A, *Organic Acids and Bases*, on the MasteringChemistry site (www.masteringchemistry.com).

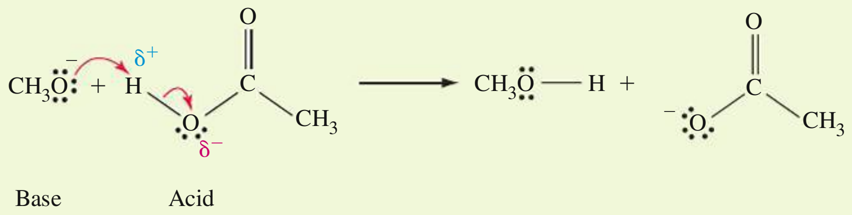
27-1 ARE YOU WONDERING...

What the difference is between a base and a nucleophile?

We have seen that a molecule or an ion having a lone pair of electrons can act as an electron pair donor in a reaction with either a proton or an electrophilic carbon atom. In both cases, a new bond is formed. When the bond is to a proton, the electron pair donor has reacted as a base. When the bond is to a carbon atom, the electron pair donor has reacted as a nucleophile. Chemists use the terms *basicity* and *nucleophilicity* when referring to the tendency of an electron pair donor to act as a base or a nucleophile in a reaction. **Basicity** is a measure of the tendency of an electron pair donor to react with a proton. **Nucleophilicity** is a measure of how readily (how fast) a nucleophile attacks an electrophilic carbon atom. We use equilibrium constants (K_b) when comparing molecules or ions in terms of their basicity, and thus basicity is an equilibrium (thermodynamic) property. When comparing molecules or ions in terms of their nucleophilicity, we are comparing them in terms of the rates at which they attack an electrophilic carbon, and thus nucleophilicity is a kinetic property.

What can make things a little confusing is that a molecule or an ion with a lone pair can act as either a base or a nucleophile. For example, the methoxide ion, CH_3O^-, is both a strong base and a good nucleophile.



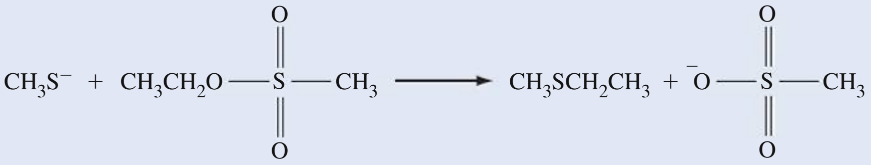


Thus, it is important to understand not only factors affecting basicity but also those affecting nucleophilicity. Factors affecting basicity are discussed in Section 27A on www.masteringchemistry.com. Factors affecting nucleophilicity are discussed on page 1221.

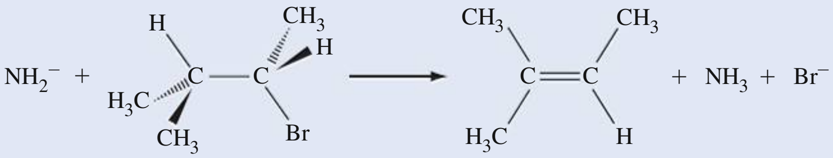
EXAMPLE 27-2 Identifying Electrophiles, Nucleophiles, Leaving Groups, Acids, and Bases

It is important to be able to distinguish when an electron pair donor in a reaction is acting as a base or as a nucleophile. The following reactions are elementary reactions. In each case, determine whether the electron pair donor is acting as a Brønsted–Lowry base or as a nucleophile. Then, identify the acid, electrophile, and leaving group, as appropriate. Finally, use arrows to indicate the movement of electrons.

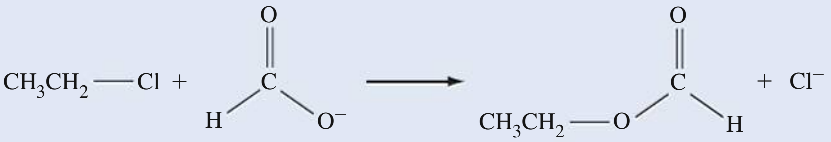
(a)



(b)



(c)

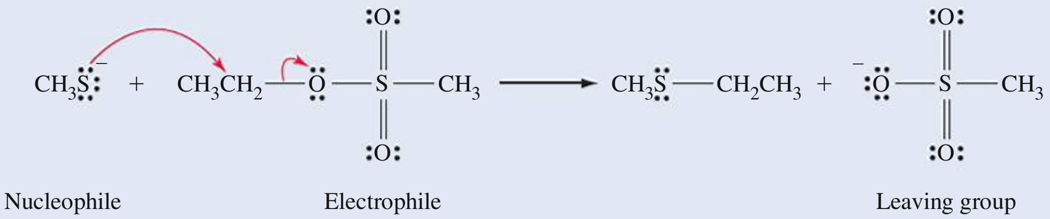


Analyze

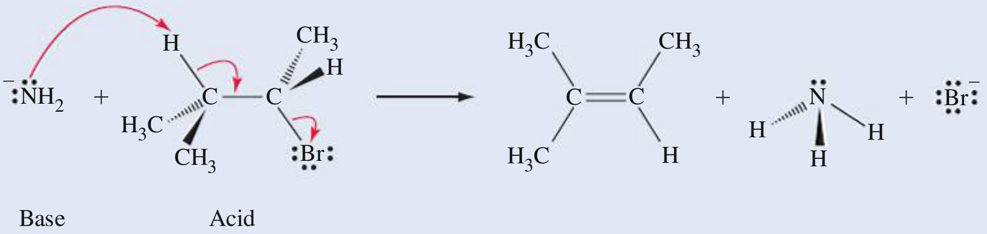
First, we put lone pairs on the atoms, and then compare reactants and products to determine which bonds are formed and which are broken. We identify the electron pair donor and the electron pair acceptor. If the electron pair donor (the attacking species) forms a new bond with a proton, it is acting as Brønsted–Lowry base. If the attacking species forms a new bond with a carbon atom, then it is acting a nucleophile.

Solve

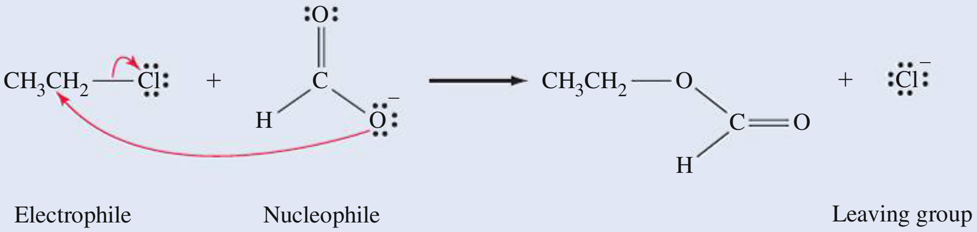
(a) In the equation below, reactants and products are shown with all lone pairs. We see that a new bond is formed between sulfur and carbon, and a bond between carbon and oxygen is broken. CH_3S^- is acting as a nucleophile, $CH_3CH_2OSO_2CH_3$ is the electrophile (or substrate), and $^-OSO_2CH_3$ is the leaving group. The red arrows indicate the movement of electrons.



(b) In this reaction, NH_2^- reacts to form NH_3. Because the chemical formulas of these species differ by a single proton, we know that NH_3 and NH_2^- are a conjugate acid–base pair. NH_2^- is acting a Brønsted–Lowry base and $(CH_3)_2CHCHBrCH_3$ is acting as an acid.



(c) We see from the equation below that a new carbon–oxygen bond is formed and a carbon–chlorine bond is broken. The HCOOH molecule is acting as a nucleophile, CH_3CH_2Cl is the electrophile, and Cl^- is the leaving group.



Assess

We can assess whether or not the substitution reactions in this example are feasible. In **(a)**, we predict that $^{-}OSO_2CH_3$ is a weaker (more stable) base than CH_3S^- because the negative charge in $^{-}OSO_2CH_3$ is highly delocalized; it is shared equally by three electronegative oxygen atoms. Thus, equilibrium favors products and we predict that the substitution will occur to a significant extent. For **(b)**, we must compare the stabilities of the bases $HCOO^-$ and Cl^-. The conjugate acid of $HCOO^-$ is HCOOH, a weak acid, and so $HCOO^-$ is a weak base. Cl^- is an extremely weak base ($pK_b \approx 21$). Because the weaker base appears on the right side of the equation, we expect reaction **(c)** will occur as written.

PRACTICE EXAMPLE A: In each of the following reactions, determine whether the electron pair donor is acting as a Brønsted–Lowry base or a nucleophile. Identify the acid, electrophile, and leaving group, as appropriate, and use arrows to indicate the movement of electrons.

(a) $CH_3I + NaOH \longrightarrow CH_3OH + NaI$

(b) $NaOH + CH_3CH_2CH_2CO_2H \longrightarrow CH_3CH_2CH_2CO_2Na + H_2O$

PRACTICE EXAMPLE B: In each of the following reactions, determine whether the electron pair donor is acting as a Brønsted–Lowry base or a nucleophile. Identify the acid, electrophile, and leaving group, as appropriate, and use arrows to indicate the movement of electrons.

(a) $NH_2Na + CH_3CH_2OH \longrightarrow CH_3CH_2ONa + NH_3$

(b) $(CH_3)_2CHCH_2CH_2Br + CH_3SNa \longrightarrow (CH_3)_2CHCH_2CH_2SCH_3 + NaBr$

The pair of curved arrows at the top of page 1213 summarizes our visualization of how electrons flow to form and break bonds. Thus, the arrow starts from an electron-rich center (the electrons on the hydroxyl group in this case) to an electron-poor region (the C atom in the polar carbon-to-chlorine bond).

This mechanism is designated $\mathbf{S_N2}$, with the S indicating substitution, the N indicating nucleophilic, and the 2 indicating that the rate-determining step is bimolecular. The reaction profile for an S_N2 reaction is shown in Figure 27-1, in which the transition state formed by the HO^- ion and the chloromethane is shown. The hydroxide attacks on the side opposite the Cl atom, and the C—Cl bond starts to break as the C—O bond simultaneously starts to form, producing the transition state shown. In the S_N2 mechanism, the nucleophile donates a pair of electrons to the electrophile to form a covalent bond.

Is there any experimental evidence to support this mechanism and postulated transition state? First, the rate law is suggestive of a bimolecular step; second, an observation by Paul Walden in 1893 confirmed the formation of the transition state as shown in Figure 27-2. Walden discovered that if the C atom bonded to the halogen is stereogenic, or chiral, the configuration at the chiral carbon is inverted—that is, the molecular structure is inverted and an enantiomer of the opposite configuration is formed. Thus, when (*S*)-2-iodobutane undergoes nucleophilic substitution by the hydroxide group, the compound (*R*)-2-butanol is formed (Fig. 27-2). This *inversion of configuration* is taken as confirmation of the proposed bimolecular mechanism and the five-coordinate transition state.

KEEP IN MIND

that the electrophile accepts the pair of electrons. Thus, the nucleophile acts as a Lewis base, and the electrophile as a Lewis acid.

Inversion of configuration in the S_N2 mechanism

The other mechanism of nucleophilic substitution at haloalkanes has a rate that is first order in the concentration of haloalkane only. For the reaction between 2-bromo-2-methylpropane and water, in which H_2O acts as the nucleophile,

$$(CH_3)_3CBr + H_2O \longrightarrow (CH_3)_3COH + HBr$$

the rate law is

$$\text{rate} = k[(CH_3)_3CBr]$$

This rate law suggests that the rate-determining step is unimolecular. The mechanism for this reaction is shown in Figure 27-3. The first step is a slow unimolecular step in which the haloalkane ionizes to form a bromide ion and a *carbocation*. The carbocation has a planar geometry and the positively charged carbon atom is sp^2 hybridized. In the second step, the carbocation immediately reacts with the nucleophile, a water molecule in this case, producing the conjugate acid of an alcohol (a protonated alcohol). The protonated alcohol dissociates immediately in the presence of excess water, forming the neutral alcohol and a hydronium ion.

This mechanism is designated **S_N1**. Again, the S indicates substitution and the N nucleophilic; in this case, the 1 indicates that the rate-determining step is unimolecular. The reaction profile for an S_N1 reaction is shown in Figure 27-4, which includes three transition states and two intermediates.

Apart from the rate law, what other evidence is there for the planar carbocation? Again, we can use a chiral haloalkane and investigate the chirality of the product. When one of the enantiomers of 3-bromo-3-methylhexane reacts

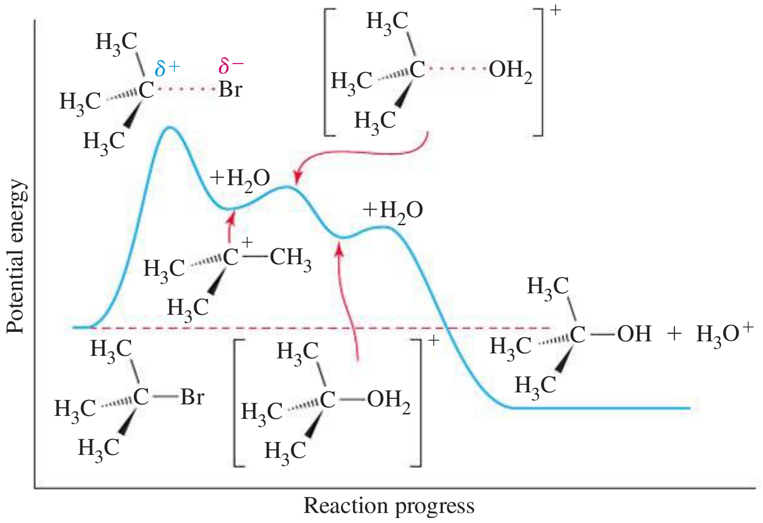
▲ FIGURE 27-3
The S_N1 Mechanism
The first step is the formation of a carbocation. It is slow and rate determining. In the second step, the electron pair donor acts as a nucleophile and attacks the electrophilic carbon atom of the carbocation, forming a σ bond.



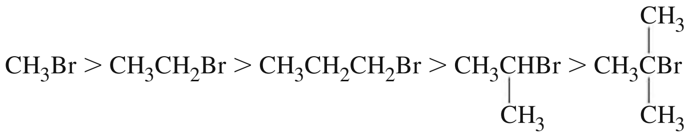
◀ FIGURE 27-4
Reaction profile for the reaction between *t*-butyl bromide and water
The carbocation formed in the rate-determining step is planar. The central C atom in the carbocation intermediate is hybridized. The remaining *p* orbital is used in the formation of the new chemical bond. The central C atom of the 2,2-dimethylethyloxonium ion (the second intermediate) becomes hybridized subsequently.

with water, the product is a racemic mixture of the enantiomers of 3-methyl-3-hexanol. The carbocation intermediate formed in the rate-determining step is planar. The water molecule (nucleophile) can form a new bond on either face of the carbocation intermediate. This results in a mixture of the product enantiomers (Fig. 27-5). The formation of a racemic mixture provides confirmation of the unimolecular rate-determining step in the S_N1 mechanism.

When is a mechanism S_N1 and when is it S_N2? To answer this question, we need to briefly discuss some kinetic studies carried out by Christopher Ingold and Edward Hughes in 1937. Measurement of rates of reaction under different sets of experimental conditions can provide insight into reaction mechanisms. For example, consider the rate of the following second-order reaction between a bromoalkane and the nucleophile Cl^-:

$$R{-}Br + Cl^- \xrightarrow{S_N2} R{-}Cl + Br^-$$

From a thermodynamic point of view, the substitution of Br^- by Cl is favorable because Br^- is a weaker base than the Cl^- ion. The *rate* of reaction shows a dramatic dependence on the degree of branching of the *α* carbon.

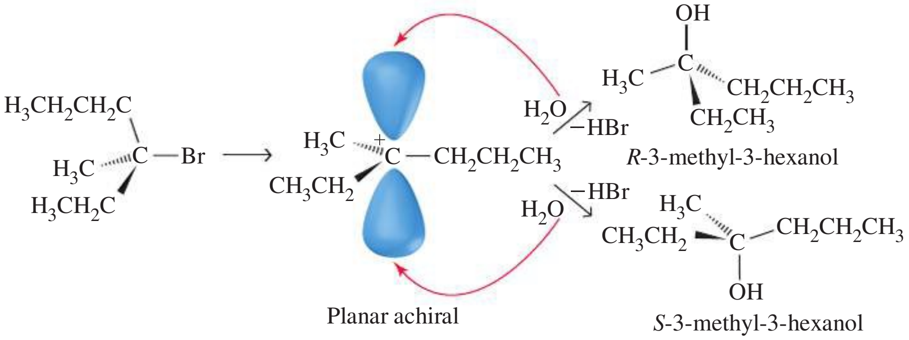


$$CH_3Br > CH_3CH_2Br > CH_3CH_2CH_2Br > CH_3\underset{\displaystyle CH_3}{\underset{|}{C}}HBr > CH_3\overset{\displaystyle CH_3}{\overset{|}{\underset{\displaystyle CH_3}{\underset{|}{C}}}}Br$$

Relative rate (for S_N2) 1200 40 16 1 Too slow to measure

◀ In the same manner that alcohols are classified as primary, secondary, and tertiary, so are haloalkanes. Thus, 2-bromopropane is a secondary haloalkane.

In the S_N2 mechanism, the nucleophile attacks the electrophilic center on the side *opposite* the leaving group, often called *backside attack*. Because the



◀ FIGURE 27-5

Bromomethane

Bromoethane

1-methylbromoethane

1,1-dimethylbromoethane

▲ FIGURE 27-6
Space-filling models of bromomethane, bromoethane, 1-methylbromoethane, and 1,1-dimethylbromoethane
The models are viewed from the vantage point of a nucleophile attacking the α carbon from the backside. As the number of methyl groups bonded to the α carbon increases, access to the partial positive charge on the α carbon decreases.

nucleophile attacks the backside of the α carbon, bulky substituents bonded to the α carbon will make it harder for the nucleophile to get to the backside. The obstruction of the nucleophile from interacting with an electrophilic carbon atom is an example of steric hindrance. Backside attack of bromomethane is fastest because there is very little steric hindrance (Fig. 27-6). However, the backside of 1,1-dimethylbromoethane is almost completely blocked from nucleophilic attack, and thus this compound does not undergo an S_N2 reaction; nucleophilic substitution occurs by an S_N1 mechanism instead.

What effect does alkyl substitution have on the rate of an S_N1 reaction? When we look at a series of bromoalkanes reacting with water, a very different order of reactivity is observed:

$$R{-}Br + H_2O \longrightarrow R{-}OH + HBr$$

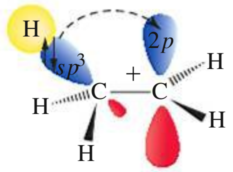
$$\begin{array}{rllll} S_N1\text{ reactivity:} & CH_3Br < & CH_3CH_2Br < & (CH_3)_2CHBr < & (CH_3)_3CBr \\ \alpha\text{ carbon:} & \text{methyl} & \text{primary} & \text{secondary} & \text{tertiary} \end{array}$$

The order of reactivity, which is the opposite of that observed for the S_N2 reaction, follows the order of carbocation stability. The reactivity is related to the stability of the carbocation because the rate-determining step in the S_N1 reaction is the formation of the carbocation (Fig. 27-4). The order of carbocation stability is as follows:

$$\text{Relative stability:}\quad \underset{\text{Least stable}}{CH_3^+} < CH_3CH_2^+ < (CH_3)_2CH^+ < \underset{\text{Most stable}}{(CH_3)_3C^+}$$

Thus, reagents or reaction conditions that favor the formation of a carbocation will increase the rate of the S_N1 reaction.

It is important to emphasize, however, that carbocations are not particularly stable, at least not in the usual sense. Carbocations are reactive intermediates with rather short lifetimes. A tertiary carbocation, such as $(CH_3)_3C^+$, has a lifetime of about 10^{-10} s in water whereas a secondary carbocation, such as $(CH_3)_2CH^+$, has a lifetime of about 10^{-12} s in water. What is the explanation for the relative stabilities of methyl, primary, secondary, and tertiary carbocations? Alkyl groups stabilize carbocations and, in that role, they appear to be electron donating. However, the explanation of how alkyl groups stabilize a carbocation is a matter of some debate. One explanation is based on the concept of *hyperconjugation*, which is illustrated in Figure 27-7 for $CH_3CH_2^+$, a primary carbocation. The positive carbon is sp^2 hybridized. Around the positively charged carbon atom is a trigonal planar arrangement of atoms and an empty $2p$ orbital perpendicular to the plane of hybridization. The adjacent carbon atom is sp^3 hybridized and forms a σ bond with a hydrogen atom. The C—H bond can donate electron density to the empty $2p$ orbital, as suggested by the dashed arrow in Figure 27-7. If more alkyl groups are present in a carbocation, then more interactions of this type occur, and a greater degree of stabilization is the result. Thus, tertiary carbocations are more stable than secondary carbocations, which are, in turn, more stable than primary carbocations. Because no alkyl groups are present in a methyl carbocation, methyl carbocations are least stable; in fact, it is assumed they are never formed.



▲ FIGURE 27-7
Stabilization of a carbocation through hyperconjugation
The carbocation is stabilized through the donation of electron density from a C—H bond to an empty $2p$ orbital on the positively charged carbon atom.

Other explanations for the stabilization of carbocations by alkyl groups are also used. However, all explanations have a common theme: the donation of electron density from filled orbitals that are aligned (or partially aligned) with the empty $2p$ orbital on the positively charged carbon atom of the carbocation. Irrespective of the explanation, alkyl groups help to stabilize a carbocation; thus, as the number of alkyl groups bonded to the α carbon increases, the stability of the carbocation also increases, as does the speed of the S_N1 reaction.

EXAMPLE 27-3 Recognizing S_N1 and S_N2 Reactions and Predicting the Products

Consider the following combinations of reactants. In each case, predict whether a substitution reaction will occur. If so, identify the products and suggest the likely mechanism.

(a) $CN^- + CH_3CH_2CH_2Cl \longrightarrow$

(b) $Br^- + CH_3CH_2OH \longrightarrow$

(c) $CH_3OH + (CH_3)_3CCl$ (in methanol) $\longrightarrow$

Analyze

To decide whether a reaction of this type will take place, we first identify the electrophile, nucleophile, and leaving group. Keep in mind that the order of reactivity for S_N2 is methyl $>$ primary $>$ secondary $>$ tertiary and that the order is the opposite for S_N1.

Solve

(a) The nucleophile is the CN^- ion, the electrophile is the chloropropane, and the leaving group is the Cl^- ion. The CN^- is a much stronger base than the Cl^- ion, and so the equilibrium constant for the reaction should be large. The chloropropane is a primary haloalkane, so the likely mechanism is S_N2 and the product will be 1-cyanopropane, $CH_3CH_2CH_2CN$.

(b) The nucleophile is the Br^- ion, the electrophile is the ethanol, and the potential leaving group is the OH^- ion. The OH^- is a much stronger base than the Br^- ion, so the equilibrium constant for the reaction is much *less* than one. No reaction is expected.

(c) The nucleophile is the CH_3OH molecule, the electrophile is the *t*-butyl chloride, and the leaving group is the Cl^- ion. In this case we have to know the relative basicities of CH_3OH and Cl^- to decide in which direction the reaction will proceed. If we assume that the basicities of methanol and chloride ion are about the same (neither likes to accept a proton), we expect an equilibrium to be established. However, the fact that we are using a large excess of methanol (methanol is the solvent) shifts the equilibrium toward the product (Le Châtelier's principle). The product is *tert*-butyl methyl ether, $(CH_3)_3COCH_3$, and the likely mechanism is S_N1 since the electrophile is a tertiary haloalkane.

Assess

In Section 27-3 we will see that other products, not just substitution products, are possible in some of these reactions.

PRACTICE EXAMPLE A: Predict whether the following reactions will take place, and suggest the likely mechanism:

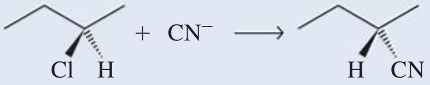
(a) $CH_3CC^- + CH_3Br \longrightarrow$

(b) $Cl^- + CH_3CH_2CN \longrightarrow$

(c) $CH_3NH_2 + (CH_3)_3CCl \longrightarrow$

PRACTICE EXAMPLE B: From the following information, identify and provide chemical equations for the mechanism of the reaction.

(a) The following reaction is carried out in acetone (propanone):



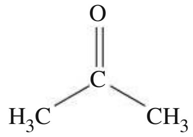
(b) A sample that contains only one enantiomer (either *R* or *S*) of an optically active compound is said to be *optically pure*. An optically pure sample of 2-iodobutane is dissolved in methanol. The resultant solution of *sec*-butyl methyl ether is optically inactive.

Solvent Effects in S_N1 and S_N2 Reactions

The nucleophile in a substitution reaction is typically a negatively charged ion or a polar molecule. Thus, to dissolve the starting materials, we must generally use polar solvents. (Recall from Chapter 13 that like dissolves like.)

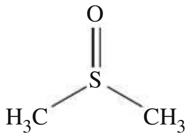
However, the nature of the solvent—in particular, the way in which solvent molecules interact with the nucleophile—plays a critical role in determining whether a reaction will follow an S_N1 or an S_N2 mechanism. To understand solvent effects, it is helpful to differentiate between protic and aprotic solvents. **Protic solvents** are solvents whose molecules have hydrogen atoms bonded to electronegative atoms, such as oxygen and nitrogen. Water, methanol, ethanol, ethanoic acid (acetic acid), and methylamine are examples of *polar* protic solvents. (Not only do these molecules have H atoms bonded to O or N, but they are also polar.) **Aprotic solvents** are solvents whose molecules do not have a hydrogen atom bonded to an electronegative element. Aprotic solvents can be polar or nonpolar, depending on whether the solvent molecules are polar or nonpolar. A few examples of polar aprotic solvents are shown in the margin. Another example (not shown) is hexamethylphosphoric triamide (HMPT), $[(CH_3)_2N]_3P{=}O$. Examples of nonpolar aprotic solvents are hexane and benzene.

Some polar aprotic solvents



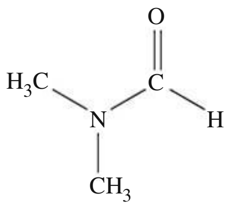
Propanone
(acetone)

Diethylether

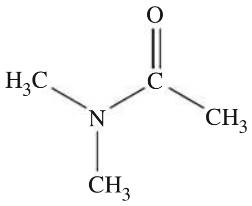


Dimethylsulfoxide
(DMSO)

Dimethoxyethane
(DME)



Dimethylformamide
(DMF)



Dimethylacetamide
(DMA)

What type of solvent favors the S_N1 pathway? The rate-determining step in an S_N1 reaction is the formation of a carbocation and an anion. If the solvent does not stabilize the ions formed in this step, an S_N1 reaction will not occur. Highly polar protic solvents, such as water and methanol, promote S_N1 reactions because the molecules of such solvents stabilize both the carbocation and the anion, in much the same way that water molecules stabilize the ions of a salt when a salt dissolves in water. (See Figure 13-6.) Molecules of a polar protic solvent stabilize carbocations through the donation of lone pairs from the oxygen or nitrogen atom, and they stabilize anions through the formation of hydrogen bonds.

What type of solvent promotes an S_N2 reaction? Polar aprotic solvents work best for S_N2 reactions. The S_N2 pathway is a concerted reaction in which the nucleophile attacks an electrophile. The reactivity of the nucleophile will be reduced if the solvent molecules are able to form hydrogen bonds with the nucleophile. When the solvent molecules form hydrogen bonds with the nucleophile, each nucleophile is surrounded by a shell of solvent molecules that impedes the reaction of the nucleophile and electrophile (Fig. 27-8). The formation of hydrogen bonds is avoided by using aprotic solvents, and thus aprotic solvents are used to promote S_N2 reactions.

▲ FIGURE 27-8
Nucleophile-solvent interactions and their effect on nucleophilicity
(a) When the ion–dipole interactions are strong, nucleophilicity is decreased. The nucleophile is strongly solvated by solvent molecules and is hindered from attacking the electrophilic carbon. **(b)** When the ion–dipole interactions are weak, the nucleophile is not strongly solvated and is less hindered by solvent molecules.

27-1 CONCEPT ASSESSMENT

Are the following solvents protic or aprotic? acetonitrile, CH_3CN; ammonia, NH_3; trimethylamine, $(CH_3)_3N$; formamide, $HCONH_2$; acetone, CH_3COCH_3.

Factors Affecting Nucleophilicity

Nucleophilicity is a measure of how readily (how fast) a nucleophile attacks an electrophilic carbon atom bearing a leaving group. But what makes a good nucleophile? It is tempting to think that there is a simple relationship between nucleophilicity and basicity because both involve the donation of an electron pair to an electrophile. No simple relationship exists because, as pointed out in Are You Wondering 27-1, nucleophilicity and basicity are fundamentally different properties. Nucleophilicity is a kinetic property (related to a rate of reaction) and basicity is a thermodynamic property (related to the thermodynamic stability of a base). Many texts correlate trends in nucleophilicity with trends in basicity. It is true that such correlations exist, but the correlations are of little use without an understanding of the underlying reasons for these correlations. The correlations exist because the explanation of trends in nucleophilicity is based, in part, on factors we use for explaining trends in basicities. For example, both nucleophilicity and basicity depend on the electronegativity, size, and hybridization of the atom bearing the lone pair; charge delocalization; and the effect of electron-withdrawing or electron-donating groups. However, trends in nucleophilicity depend on other factors too, such as the interactions between the nucleophile and solvent molecules, steric effects, and the nature of the electrophile. Therefore, trends in nucleophilicity do not always follow trends in basicity.

Let us consider a few principles that we can use for understanding trends in nucleophilicity. When applying these principles, our point of reference is the nucleophilic atom, which possesses the lone pair that is used to form a bond with the electrophile. As we work our way through these principles, we will see similarities to explanations given earlier (Section 27A on www.masteringchemistry.com), but it is important that we take careful note of the differences.

1. All else being equal, a negatively charged nucleophile will react faster than an uncharged nucleophile. For example, HO^- is a stronger nucleophile than H_2O, and CH_3O^- is a stronger nucleophile than CH_3OH. A negatively charged atom is more strongly attracted to an electrophilic center than is an atom having no charge or a partial negative charge.
2. When comparing molecules or ions in which the nucleophilic atoms are from the *same row of the periodic table*, the electronegativity of the nucleophilic atom is an important factor because it affects how available the lone pair will be for bonding to the electrophilic atom. In the following anions, the nucleophilic atoms are from the second period.

Increasing electronegativity of the nucleophilic atom

$$\xrightarrow{\hspace{6cm}}$$

$$H_3C^- > H_2N^- > HO^- > F^-$$

$$\xleftarrow{\hspace{6cm}}$$

Increasing nucleophilicity

F^- is not as good a nucleophile as H_3C^- because F is more electronegative than C, and thus a lone pair on F^- is less available for bonding than is the lone pair on H_3C^-.

It is sometimes possible to predict the effect of other factors, such as charge delocalization or the presence of electron-withdrawing or electron-donating groups. Consider, for example, the following series of nucleophiles, arranged in order of decreasing nucleophilicity (from strongest to weakest). All the nucleophilic atoms in these ions are from the second period.

$$\underleftarrow{H_2N^- > CH_3O^- > HO^- > HCOO^-}$$

Increasing nucleophilicity

H_2N^- is the strongest nucleophile because N is less electronegative than O, and thus the lone pair on N is more available for bonding than is a lone pair on O. CH_3O^- is a stronger nucleophile than HO^- because, in solution, the CH_3 group is electron donating and this helps to make the lone pairs on O less stable and more reactive. $HCOO^-$ is a weaker electrophile than HO^- because the negative charge is delocalized (shared equally by both oxygens), and thus $HCOO^-$ will be less reactive than HO^-.

3. Negatively charged nucleophiles are more reactive in polar aprotic solvents than they are in polar protic solvents. In a polar protic solvent, anions are more highly solvated and thus less reactive (Fig. 27-8).

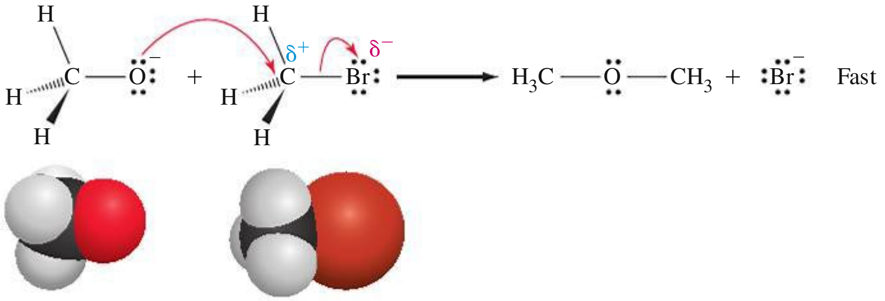
   The importance of considering how the solvent affects nucleophilicity cannot be overstated. The trend in reactivities of a series of nucleophiles can, in some instances, be completely reversed by changing the solvent.

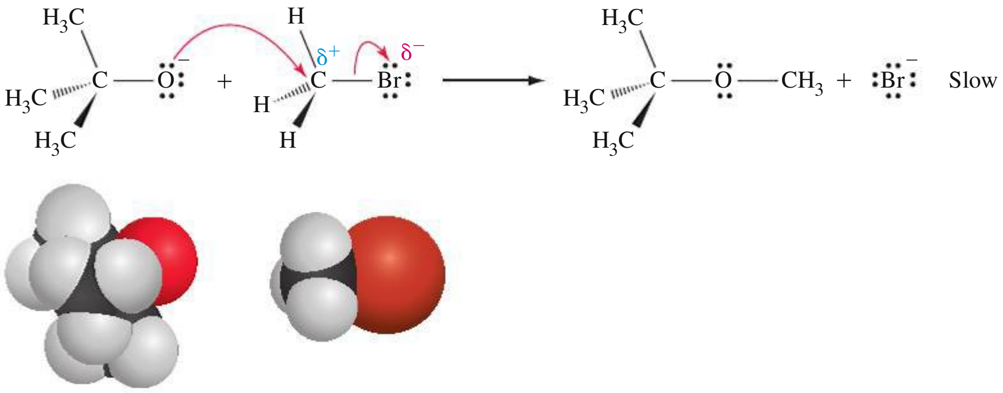
Protic solvent: $I^- > Br^- > Cl^- > F^-$

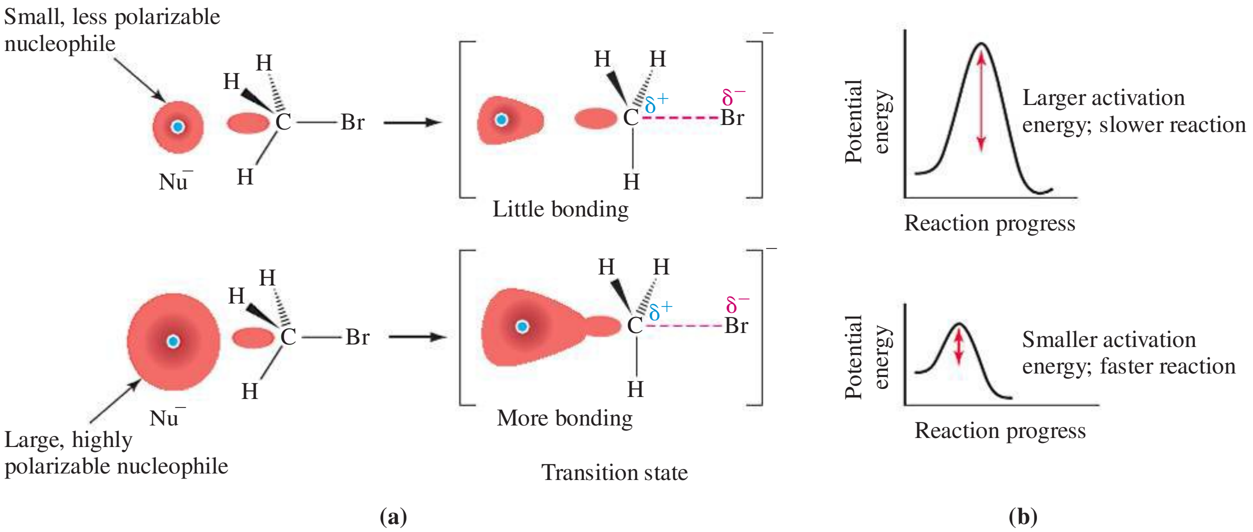
Aprotic solvent: $\underleftarrow{F^- > Cl^- > Br^- > I^-}$

Increasing nucleophilicity

4. When comparing nucleophiles in which the nucleophilic atoms are from *the same group*, nucleophilicity *usually* increases as the size (and thus, polarizability) of the nucleophilic atom increases. The larger and more polarizable the nucleophilic atom, the easier it is for the charge cloud of the nucleophile to be distorted toward the electrophilic carbon atom. The distortion of the charge cloud toward the electrophilic carbon atom helps to lower the energy of the transition state and increases the rate of reaction. (See Figure 27-9.)
5. Bulky groups adjacent to the nucleophilic atom reduce the reactivity of a nucleophile because these groups hinder the approach of the nucleophile toward the electrophilic atom. For example, consider the relative reactivities of the methoxide and *tert*-butoxide ions:







Small, less polarizable nucleophile

Transition state
Smaller activation energy; faster reaction
(a)
(b)

▲ FIGURE 27-9

The effect of the polarizability of the nucleophile in an S_N2 reaction

For simplicity, the nucleophile is represented by a spherical charge distribution. **(a)** The formation of the transition state in the S_N2 mechanism involves transfer of electron density from the nucleophile to a vacant orbital localized on C. For the larger and more polarizable nucleophile, the transfer of electron density occurs sooner (at larger distances) and the resulting transition state is of lower energy, as shown in **(b)**. Because the rate of reaction increases as the activation energy decreases, the more polarizable nucleophile reacts faster. Keep in mind that solvent-nucleophile interactions (not shown) also affect the ability of the nucleophile to bond with the electrophilic carbon atom.

As indicated by the space-filling models of the $(CH_3)_3CO^-$ and CH_3O^- ions, the nucleophilic oxygen atom of $(CH_3)_3CO^-$ is significantly hindered from closely approaching the electrophilic carbon atom of CH_3Br but the oxygen atom of CH_3CO^- is not. Consequently, $(CH_3)_3CO^-$ is a weaker nucleophile than CH_3O^-.

In Table 27.1 we classify some commonly encountered nucleophiles as excellent (strong), good, and fair. However, it is important that we use the information in this table cautiously. The preceding discussion makes it clear that the nucleophilicity of an electron pair donor is influenced by several factors, only some of which are related to the structure of the nucleophile itself. Nucleophilicity depends also on the solvent used and the nature of the electrophile. A given electron pair donor may behave as a strong nucleophile in a particular situation, but it may not be a strong nucleophile in another.

A Summary of S_N1 and S_N2 Reactions

In this section, we considered two different mechanisms by which a substitution reaction at an sp^3-hybridized carbon atom occurs. It is important to remember that (1) S_N1 and S_N2 reactions compete with each other, and (2) the exact details of any particular reaction might place it somewhere between these two mechanistic extremes. With an appropriate selection of reactants and reaction conditions, we might be able to push a particular reaction toward one mechanism or the other. Ultimately, the molecules in a system will always react by the lowest energy pathway. Depending on the reactants and reaction conditions, the lowest energy pathway for a substitution reaction may be the S_N1 reaction or the S_N2 reaction or something in between these two extremes. Table 27.2 summarizes some key ideas from this section and identifies the combinations of reactants and reaction conditions that push a substitution reaction toward either the S_N1 or S_N2 mechanism.

TABLE 27.1 Classification of Common Nucleophiles

Excellent Nucleophiles		
		Rate[a]
NC^-	Cyanide	126,000
HS^-	Thiolate	126,000
I^-	Iodide	80,000
Good Nucleophiles		
		Rate
HO^-	Hydroxide	16,000
Br^-	Bromide	10,000
N_3^-	Azide	8,000
NH_3	Ammonia	8,000
NO_2^-	Nitrite	5,000
Fair Nucleophiles		
		Rate
Cl^-	Chloride	1,000
CH_3COO^-	Acetate	630
F^-	Fluoride	80
CH_3OH	Methanol	1
H_2O	Water	1

[a] The rate is a relative rate. A rate of 100 means that the nucleophile reacts 100 times as fast as water does.

TABLE 27.2 Relative Reactivities of Haloalkanes

Electrophile	 $H_3C-C(CH_3)_2-X$ 3°	 $H_3C-CH(CH_3)-X$ 2°	 $H-CH(CH_3)-X$ 1°	 $H-CH_2-X$ Methyl

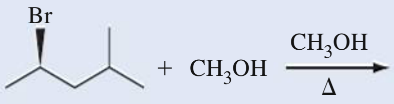
EXAMPLE 27-4 Predicting Whether a Substitution Reaction Proceeds by an S_N1 or S_N2 Mechanism

Does the substitution reaction below follow an S_N1 or an S_N2 mechanism? What are the products? Write the steps of the mechanism and use arrows to show the movement of electrons.



(*R*)-2-bromo-4-methylpentane

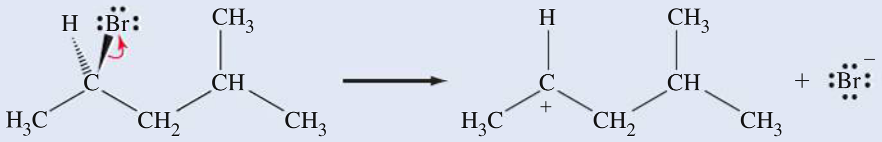
Analyze

The haloalkane is a 2° haloalkane. Secondary haloalkanes undergo substitution reactions by either the S_N1 or S_N2 depending on the nucleophile and solvent. (See Table 27.2.)

Solve

Methanol is the nucleophile and the haloalkane is the electrophile. Because the nucleophile is uncharged, its nucleophilicity is determined primarily by the polarizability of the nucleophilic atom (O). The O atom is relatively small and not very polarizable; thus, CH_3OH is a weak nucleophile. A weak nucleophile disfavors an S_N2 reaction. Also, the solvent is polar protic and will help to stabilize a carbocation. With a weak nucleophile and a polar protic solvent, we expect the substitution reaction to occur by an S_N1 mechanism. The carbocation that is formed reacts with a solvent molecule CH_3OH (a *solvolysis reaction*) to form a protonated ether. The final product is an ether, which is obtained when a proton is transferred from the protonated ether to a CH_3OH molecule from the solvent. We will obtain two products, the *R* and *S* stereoisomers, because CH_3OH can attack the carbocation from either side. The steps are as follows:

Step 1: Formation of a carbocation



Step 2: Nucleophilic attack by CH_3OH

Thus, the reaction will produce a racemic mixture consisting of the (*R*) and (*S*) stereoisomers of 2-methoxy-4-methylpentane.

Assess

To name the products, you may find it helpful to review the nomenclature rules given in Chapter 26. The reaction considered in this example is also called a solvolysis reaction, because the solvent acts as the nucleophile.

PRACTICE EXAMPLE A: Predict whether the substitution product obtained in the reaction below follows an S_N1 or an S_N2 mechanism. Show all steps in the mechanism, using arrows to indicate the movement of electrons. Name the product.

27-3 Introduction to Elimination Reactions

In the previous section, we saw that a haloalkane can undergo a substitution reaction in which the halogen atom is replaced by another group. Haloalkanes can also undergo elimination reactions, in which the halogen atom and a hydrogen atom bonded to the β carbon are removed from the molecule.

+ H
X

(27.3)

As is true for substitution reactions, elimination reactions of haloalkanes can occur by different mechanisms. If the rate-determining step is unimolecular, then the mechanism is called **E1**. If the rate-determining step is bimolecular, the mechanism is called **E2**. In this section, we will explore these mechanisms in some detail and discuss the competition that occurs between elimination and substitution reactions.

The E1 and E2 Mechanisms

In all the reactions we have examined so far, the electron pair donor reacted exclusively as either a base or a nucleophile. However, the situation is hardly ever so simple. For example, when 2-bromo-2-methylpropane, a tertiary haloalkane, is dissolved in methanol, two different products are obtained. The major product (81%) is the expected substitution product, 2-methoxy-2-methylpropane. The reaction proceeds via the S_N1 mechanism.

2-methylpropene
(19%)

Kinetic studies show that the rate of this reaction depends on the concentration of the haloalkane only:

$$rate = k[(CH_3)_3CBr]$$

Because the reaction is an elimination reaction following first-order kinetics, it is called an **E1 reaction**. The mechanism for this E1 reaction is shown in Figure 27-10. The first step is a slow step involving the formation of a carbocation. This step is identical to the first step in the S_N1 mechanism. In the second step, a methanol molecule reacts as a base (not as a nucleophile) and removes a proton from the carbocation, yielding an alkene. Notice that a proton is removed from a carbon atom adjacent to the positively charged carbon atom of the carbocation, a β carbon. The reaction profile is shown in Figure 27-11.

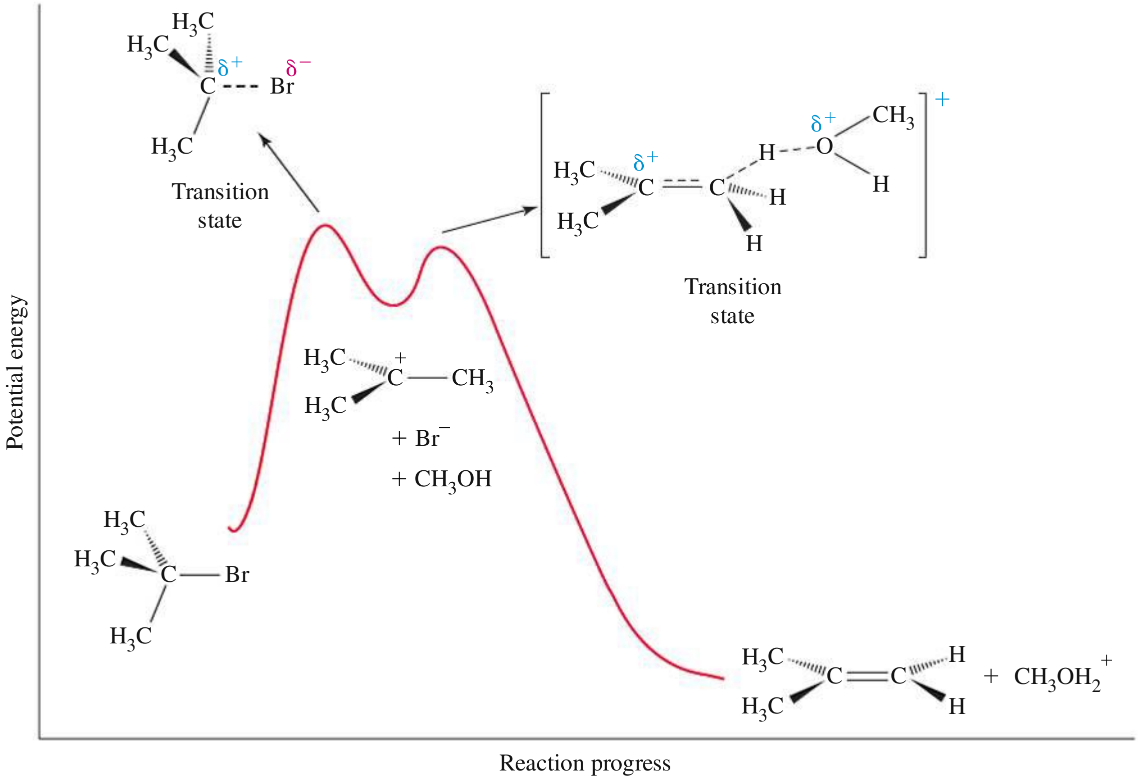
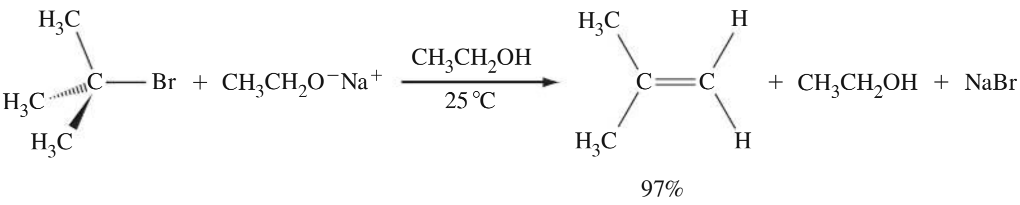
▶ FIGURE 27-10
The E1 mechanism
The first step is the formation of a carbocation. It is slow and rate determining. The second step is an acid–base reaction in which a proton is removed from a carbon atom adjacent to the positively charged carbon atom of the carbocation.



▲ FIGURE 27-11
Reaction profile for the E1 reaction between *tert*-butylbromide and methanol
The first step is a highly endothermic process involving the formation of a carbocation. In the transition state for the first step, the C—Br bond is partially broken. In the second step, CH_3OH acts as a base and removes a proton from the β carbon. In the transition state for the second step, a new π bond is forming between two C atoms. In addition, a C—H bond is breaking and a new H—O bond is forming.

When we compare the E1 mechanism to the S_N1 mechanism (Fig. 27-4), we see why the reaction of $(CH_3)_3CBr$ and CH_3OH yields a mixture of two products. After the formation of the carbocation, methanol can act like a nucleophile and attack the electrophilic carbon atom (producing the S_N1 product) or it can act as a base and remove a proton to produce an alkene. The essential difference between the S_N1 and E1 mechanism is the role played by the electron pair donor in the second step. In the S_N1 mechanism, the electron pair donor acts as a nucleophile and forms a σ bond with the electrophilic carbon atom of the carbocation. In the E1 mechanism, the electron pair donor acts as a base and forms a σ bond with a proton.

In the example we just considered, the nucleophile was CH_3OH. The CH_3OH molecule is a weak nucleophile (it is a neutral molecule and the nucleophilic atom is relatively small and not very polarizable) and also a weak base. Let us consider what would happen in the reaction of $(CH_3)_3CBr$ and CH_3CH_2ONa in ethanol, bearing in mind that the $CH_3CH_2O^-$ ion is a stronger base than CH_3OH. We anticipate that the amount of alkene in the product mixture will increase, and as the equation below shows, this is in fact what is observed:



A study of the kinetics of this reaction reveals, however, that the rate of elimination depends on the concentrations of the substrate and the base:

$$rate = k[(CH_3)_3CBr][CH_3CH_2O^-]$$

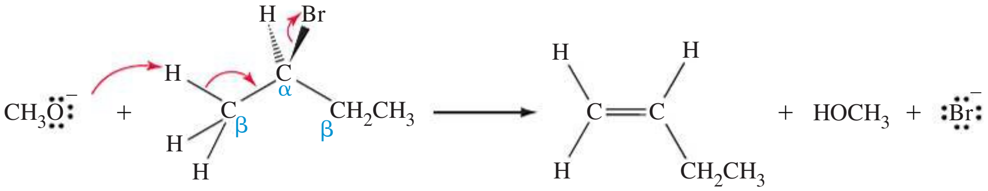
Whereas the use of a stronger base promotes elimination at the expense of substitution, we can see that the mechanism of the elimination reaction cannot be the E1 mechanism. (Recall that the rate of an E1 reaction depends only on the concentration of the substrate.) Because the kinetics of this elimination reaction are second order, the rate-determining step must be bimolecular. Thus, the reaction is called an **E2 reaction**. Detailed studies of E2 reactions reveal that the E2 mechanism consists of a single step that proceeds through a single transition state where three changes are occurring simultaneously: (1) removal of a proton from the β carbon; (2) departure of the leaving group; (3) formation of a π bond between the α and β carbon atoms. The reaction profile for the E2 reaction between $(CH_3)_3CBr$ and $CH_3CH_2O^-$ is illustrated in Figure 27-12.

27-2 CONCEPT ASSESSMENT

The principal product in the reaction of $(CH_3)_3CBr$ and $NaCH_3CH_2O$ in ethanol is an alkene. What is the minor product and by what mechanism is it formed?

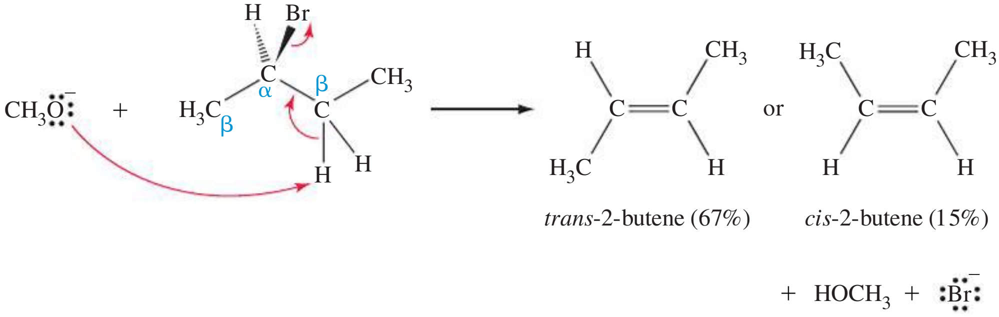
Predicting the Major Elimination Product

In the elimination reactions that we have studied so far, only one elimination product was possible. However, it is often the case that more than one elimination product can be produced. For example, in the reaction of 2-bromobutane with sodium methoxide in methanol, three E2 products are possible:



1-butene (18%)

(27.4a)



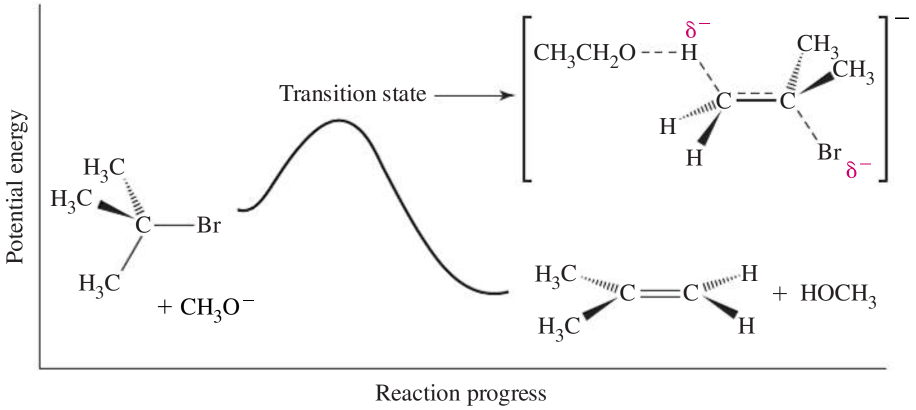
(27.4b)

KEEP IN MIND

that the product mixture for an elimination reaction will be richer in the product that is formed the fastest. The relative rates of the elimination reactions are determined by the energies of the corresponding transition states. For an elimination reaction, the transition state has some double bond character, and so the factors known to stabilize an alkene will also stabilize the transition state. As a consequence, the pathway that leads to the more stable alkene usually also passes through the transition state of lowest energy; thus, the reaction leading to the most stable alkene is not only the most exothermic but also the fastest.

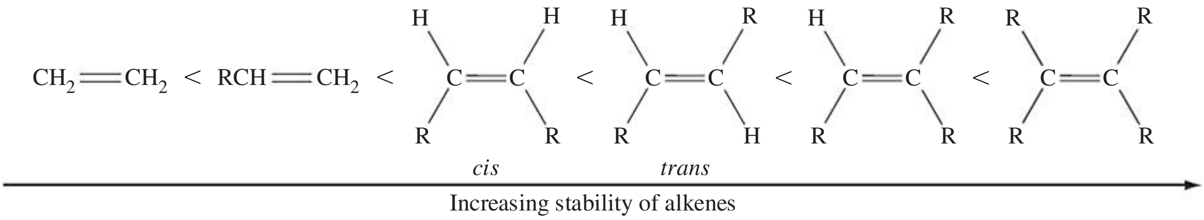
In 1-butene, the double bond is at the end of the carbon chain (a terminal C═C bond) and in the *cis* and *trans* isomers of 2-butene, the C═C bond is an internal double bond. Notice that there is a strong preference or selectivity for forming the internal double bond (82% versus 18%).

When more than one elimination product is possible, can we reliably predict which will be the major product? Usually, the major product of an elimination reaction is the one that is most stable. But what can we say about the relative



◀ FIGURE 27-12
Reaction profile for the E2 reaction of $(CH_3)_3Br$ and $CH_3CH_2O^-$ in methanol

stabilities of alkenes? In the diagram below, alkenes are ranked in order of increasing stability:



This order of stability is based on experimental data (heats of hydrogenation). The following statement summarizes the trend in stabilities:

> The greater the number of alkyl substituents bonded to the sp^2 carbons of an alkene, the greater its stability.

In general, more highly substituted alkenes are more stable than less highly substituted alkenes. Also, bulky alkyl groups like to be as far as apart as possible, and so, for example, the *trans* isomer is more stable than the *cis* isomer.

Let's return to reaction (27.4) and rationalize the product distribution that is obtained. The alkenes having an internal double bond are the major products because they are more highly substituted and the transition states leading to these alkenes are lower in energy than the transition state leading to the less highly substituted alkene. Thus, the alkenes having the internal double bonds are formed the fastest and are the major components of the product mixture. Of the two alkenes having an internal double bond, the *trans* stereoisomer is the more stable (and the transition state leading to this stereoisomer is lower in energy) and thus, the *trans* isomer is the major product.

A word of caution is in order. Often, the major product in an elimination reaction is the most highly substituted alkene but important exceptions exist to this rule. The formation of the most highly substituted alkene requires that the base remove a proton from a secondary or tertiary carbon atom. Access to the hydrogen atoms on a secondary or tertiary carbon atom is hindered by the adjacent groups. Small bases, such as OH^-, CH_3O^- or $CH_3CH_2O^-$, can get past these groups fairly easily but larger bases, such as $(CH_3)_3CO^-$, cannot. A large base will preferentially attack the more exposed hydrogen atoms, yielding the least highly substituted alkene. In the following reactions, the same substrate reacts with different bases. In the first reaction, a smaller, less hindered base is used and the major elimination product is the more highly substituted alkene. In the second reaction, a larger, more hindered base is used and the major elimination product is the less highly substituted alkene.

◀ The explanation of why the stability of an alkene increases with the degree of alkyl substitution is a matter of some conjecture. A common explanation is based on the concept of *hyperconjugation*. According to IUPAC, in the formalism that separates bonds into σ and π types, hyperconjugation is the interaction of σ bonds (e.g., C—H, C—C, etc.) with a π network. Other explanations are based on the interactions of filled and empty molecular orbitals and call into question the appropriateness of using hyperconjugation as an explanation. Even in the absence of an explanation, the experimental facts are unambiguous: The stability of an alkene increases with the number of alkyl groups on the carbon atoms of the double bond.

For an E2 reaction, the H atom on the β carbon must be "anti" to the leaving group. This requirement places a restriction on the elimination products that can be formed from a 2° haloalkane. For a more detailed discussion and a worked example involving an elimination reaction, see Section 27B, *A Closer Look at the E2 Mechanism*, on the MasteringChemistry site (www.masteringchemistry.com).

MasteringCHEMISTRY

Substitution and Elimination Reactions: A Summary

We have seen that haloalkanes can undergo a variety of reactions: S_N2, S_N1, E2, or E1. In principle, all these reactions compete with one another, and a variety of products are possible. When determining whether a reaction will proceed through an S_N2, S_N1, E2, or E1 mechanism, we must consider many factors. What is the nature of the electron pair donor? Is it a good nucleophile? Is it a strong base? Is it sterically hindered? What is the nature of the electrophile? Is it sterically hindered? And what about the solvent? Does it promote carbocation formation (S_N1/E1 reactions)? Does it increase or decrease the nucleophilicity of the electron pair donor?

With all these factors to consider, it is natural to ask: Is it possible to predict reliably the outcome of a reaction and the mechanisms that are involved? The answer to this question is a tentative yes. There are some guiding principles, which we present in Figure 27-13, but remember that exceptions to these guidelines exist. To make the best use of these guidelines, the following stepwise approach is recommended:

1. Show all formal charges and partial charges on atoms that have them.
2. Identify the electron pair donor and the electron pair acceptor (the electrophile).
3. Consider the electrophile. Is it primary, secondary, or tertiary?
4. Consider the electron pair donor. Is it a strong or weak nucleophile? Is it a strong or weak base? Is it sterically hindered?
5. Is the solvent protic or aprotic?
6. Determine whether the dominant reaction will be S_N2, E2, or S_N1 and E1. (Remember that S_N1 and E1 always occur at the same time.)

Before we attempt to apply this approach to specific cases, let's have a look at the guidelines summarized in Figure 27-13. The guidelines are presented in the form of a decision tree, with the first consideration being the base strength of the electron pair donor, $:\text{B}$. Additional considerations include steric hindrance, nucleophilicity, and solvent effects.

For primary alkanes (Figure 27-13a), the possible reactions are S_N2 and E2. An S_N1 reaction is not a likely possibility because primary carbocations are not

▲FIGURE 27-13

Summary of S_N2, E2, S_N1, and E1 reactions for primary, secondary, and tertiary haloalkanes

(a) Primary haloalkanes undergo S_N2 or E2 reactions. **(b)** Secondary haloalkanes undergo S_N2, E2, S_N1, and E1 reactions. The red boxes indicate there are additional considerations. For an alkene with internal C=C bond, the possibility of (*E*) and (*Z*) stereoisomers exists. When a secondary haloalkane undergoes an S_N2 reaction, watch for an inversion of configuration, (*R*) ↔ (*S*). In polar protic solvents, a secondary haloalkane can react with a weak nucleophile to give S_N1 and E1 products. **(c)** Tertiary haloalkanes undergo S_N1, E1, and E2 reactions. Methyl halides (CH_3X) are not included because the methyl halides undergo only S_N2 reactions.

stable. If the electron donor, :B, is a sterically hindered strong base, such as R_3CO^-, then the E2 reaction will dominate because the electron donor will not be able to attack the electrophilic carbon atom from the backside. Instead, a proton will be removed from a β carbon. If :B is not sterically hindered, then it will act as a nucleophile and attack the electrophilic carbon from the backside in an S_N2 reaction. If :B is a strong nucleophile, such as I^-, ^-CN, RS^-, or RO^-, then the S_N2 reaction will occur quite rapidly. If :B is a weak nucleophile, then the S_N2 reaction will occur rather slowly.

The greatest range of possibilities occurs for secondary haloalkanes (Fig. 27-13b). If the electron donor is a strong base, then elimination by E2 is the main reaction and the major product is an alkene with an internal C=C bond. If :B is a weak base but a strong or good nucleophile, such as I^-, ^-CN,

RS^-, or RCO_2^-, then the main reaction will be S_N2, particularly if a polar aprotic solvent is used. It is important to remember that if the α carbon in the haloalkane is chiral, then the S_N2 reaction will invert the configuration of the α carbon. If : B is a weak base and also a poor nucleophile, such as H_2O or ROH, then the S_N1 reaction will dominate provided a polar protic solvent is used. Molecules of the solvent will most likely act as the nucleophile in this case. E1 products will also form along with the S_N1 products.

For tertiary haloalkanes (Figure 27-13c), the possible reactions are S_N1 E1, or E2. An S_N2 reaction is not very likely because the α carbon is too sterically hindered for backside attack. If : B is a strong base, such as R_3CO^- or RO^-, then elimination by E2 will be the dominant reaction. If : B is a weak base (and a poor nucleophile), such as H_2O or ROH, then the main reaction will be S_N1 with some E1 products being formed as well, provided a polar protic solvent is used. It is important to remember that if the α carbon is chiral, the S_N1 products will consist of a mixture of (*R*) and (*S*) stereoisomers.

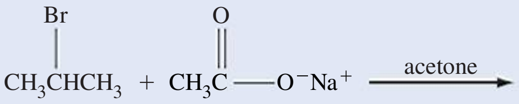
In Example 27-5, we illustrate how the guidelines summarized in Figure 27-13 can be used to predict the products that will be obtained in a given situation and the mechanisms by which these products will be formed.

EXAMPLE 27-5 Predicting S_N2, E2, S_N1, and E1 Reactions

For each of the following reactions, predict the products and the mechanisms by which the products are formed.

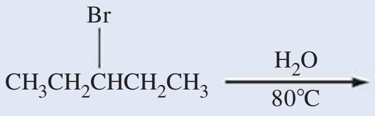
(a) $CH_3CH_2CH_2CH_2Br + (CH_3)_3CO^-Na^+ \xrightarrow{(CH_3)_3COH}$

(b)



$CH_3CHBrCH_3 + CH_3C(=O)O^-Na^+ \xrightarrow{\text{acetone}}$

(c)



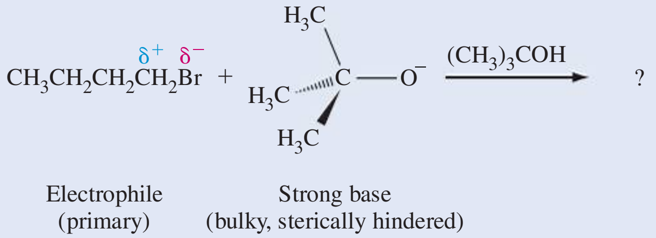
$CH_3CH_2CHBrCH_2CH_3 \xrightarrow[80°C]{H_2O}$

Analyze

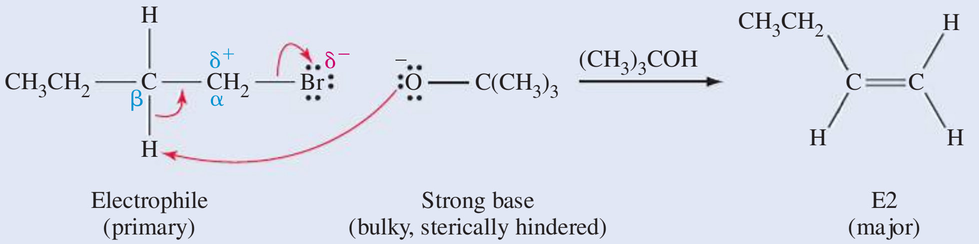
We follow the six-step approach outlined above and use the decision tree in Figure 27-13 to guide our thinking.

Solve

(a) We identify the electrophile as $CH_3CH_3CH_2Br$, which is a primary haloalkane. The nucleophile is $(CH_3)_3CO^-$, a sterically hindered strong base.

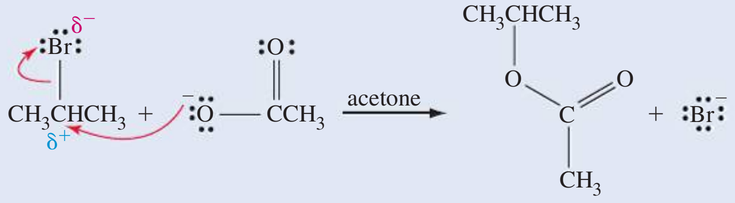


Although a strong base is usually a strong nucleophile, the bulkiness of this base disfavors substitution, and we expect that elimination by E2 will provide the major product.



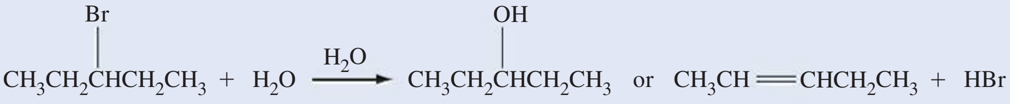
Substitution by S_N2 will yield $CH_3CH_2CH_3CH_2OC(CH_3)_3$, but the substitution product will be the minor product.

(b) The electrophile is a secondary haloalkane. The electron pair donor is a weak base (the conjugate base of a weak acid) and, because it is negatively charged, it is a reasonably good nucleophile, especially in a polar aprotic solvent. We expect that the main reaction will be S_N2.



Electrophile (secondary) — Weak base (good nucleophile) — S_N2 product (major)

(c) Molecules of the solvent also serve as the electron pair donor. The reaction involves a secondary haloalkane with a weak base/weak nucleophile in a polar protic solvent. These conditions do not favor S_N2 or E2 but rather S_N1 and E1. S_N1 and E1 always occur together. Secondary carbocations are relatively stable, especially in a polar protic solvent, such as water. We expect both S_N1 and E1 products. Because H_2O is a very weak base and a fair nucleophile, substitution will dominate over elimination.

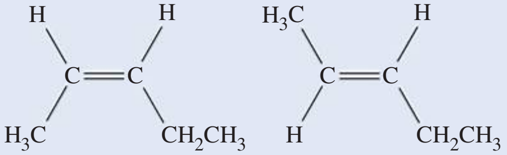


$$CH_3CH_2\overset{Br}{\overset{|}{C}}HCH_2CH_3 + H_2O \xrightarrow{H_2O} CH_3CH_2\overset{OH}{\overset{|}{C}}HCH_2CH_3 \text{ or } CH_3CH{=}CHCH_2CH_3 + HBr$$

Electrophile (secondary) — Weak base (weak nucleophile) — S_N1 (major) — E1 (minor)

Assess

The mechanism for the reaction in **(c)** was not explicitly shown. We must make sure we are able to show the steps involved in forming the S_N1 and E1 products, including using arrows to show the movement of electrons. Also in **(c)**, (*E*) and (*Z*) isomers of 2-pentene are possible.

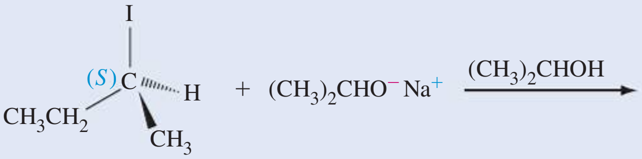


(*Z*)-2-pentene (*E*)-2-pentene

PRACTICE EXAMPLE A: For the following reaction, predict the major product and the mechanism by which it is formed:

$$CH_3CH_2CH_2Br + CH_3S^-Na^+ \xrightarrow{\text{acetone}}$$

PRACTICE EXAMPLE B: Predict the substitution and elimination products that are possible in the following reaction. Which is the major product?

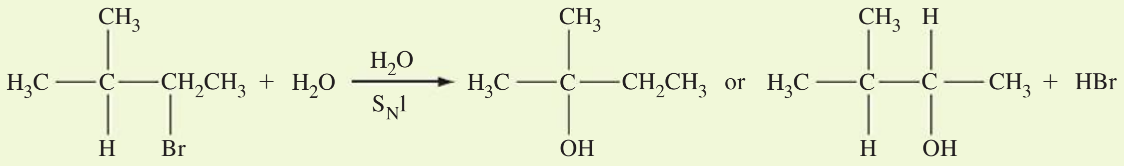


27-2 ARE YOU WONDERING...

Whether S_N1/E1 reactions of haloalkanes are used in organic synthesis?

The summary given at the end of Section 27-3 highlighted the fact that S_N1 and E1 reactions always occur together. We also know that once the carbocation in these reactions is formed, it is susceptible to attack from a variety of species. Consequently, the S_N1 and E1 reactions of haloalkanes are not often used for synthesizing other organic compounds.

Another complication that arises with S_N1 and E1 reactions is the rearrangement of the carbocation intermediate to form a more stable intermediate before the S_N1 or E1 product is formed. Such a situation arises, for example, when 2-bromo-3-methylbutane is heated with water. The major S_N1 product is not 3-methyl-2-butanol but rather 2-methyl-2-butanol.

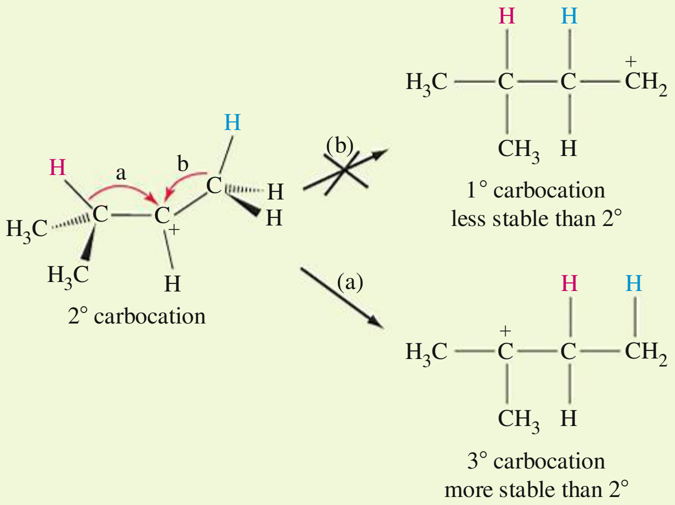


2-bromo-3-methylbutane

2-methyl-2-butanol (major)

3-methyl-2-butanol (minor)

The major product is produced following the rearrangement of the 2° carbocation that is formed when the carbon–bromine bond in 2-bromo-3-methylbutane breaks to release a Br^- ion. As suggested below, two possible rearrangements, labeled (a) and (b), can occur. Both rearrangements involve the movement of a hydrogen atom. These rearrangements are examples of a *hydride shift*.



Rearrangement (b) does not occur because it results in a 1° carbocation, which is highly unstable. Rearrangement (a) converts a 2° carbocation into a more stable 3° carbocation. The 3° carbocation is the one that leads to the major substitution product.

Anytime a carbocation ion forms, rearrangement of the carbocation is always a possibility. To make matters worse, the rearrangement can also involve the movement of methyl groups or alkyl chains.

Given the myriad possibilities that can arise in S_N1 and E1 reactions, and the difficulty in predicting or controlling what will happen, it comes as no surprise that S_N1 and E1 reactions are not used as often as other reactions for organic synthesis.

27-4 Reactions of Alcohols

Alcohols figure prominently in organic synthesis because they can be readily converted into other compounds. In Chapter 26, we saw that primary alcohols could be oxidized to aldehydes or carboxylic acids and secondary alcohols could be oxidized to ketones. We also mentioned that alcohols react with carboxylic acids to form esters. In Section 27-2, we saw examples of reactions in

TABLE 27.3 Some Reactions of Alcohols

Type of Reaction	Equation
Deprotonation	$ROH + Na \longrightarrow RO^{-}Na^{+} + 1/2\,H_2$
Oxidation[a]	$ROH \xrightarrow{[O]}$ aldehyde, ketone or carboxylic acid
Esterification	$ROH + R'COOH \xrightarrow[\Delta]{H^+} R'COOR + H_2O$
Substitution	$ROH^{b} + R'X \longrightarrow ROR' + HX$ $ROH^{c} + HX \longrightarrow RX + H_2O$
Elimination	$ROH \xrightarrow[\Delta]{H^+}$ alkenes

[a] In the equation for oxidation, [O] represents the oxidizing agent, such as $Na_2Cr_2O_7/H_2SO_4$ or PCC/CH_2Cl_2. PCC is pyridinium chlorochromate. See page 1185.
[b] ROH is acting as a nucleophile in this reaction. See Section 27-2.
[c] ROH is acting as an electrophile in this reaction.

which an alcohol (ROH) reacted as a nucleophile in a substitution reaction with a haloalkane (R′X) to form an ether (ROR′). Some of the reactions of alcohols are summarized in Table 27.3.

In this section, we focus on reactions in which the —OH group is replaced by a halogen atom (in a substitution reaction) or eliminated as H_2O (in an elimination reaction).

Substitution and Elimination Reactions of Alcohols

The —OH group of an alcohol can be replaced by a halogen atom or eliminated as H_2O under appropriate conditions. Let's consider the feasibility of the following substitution reactions by using concepts we've discussed previously in this chapter.

$$CH_3CH_2CH_2OH + NaI \longrightarrow CH_3CH_2CH_2I + NaOH \quad \text{(does not occur)}$$
$$CH_3CH_2CH_2OH + HI \xrightarrow{\Delta} CH_3CH_2CH_2I + H_2O \quad \text{(occurs slowly)} \qquad \textbf{(27.5)}$$

In both of these reactions, I^- is the nucleophile and OH^- is the leaving group. Although the I^- ion is a good nucleophile, the OH^- ion is strongly basic and a poor leaving group. Consequently, the first reaction does not occur. Why does the second reaction occur? In the presence of strong acid, the oxygen atom of the —OH group is protonated, forming $R{-}\overset{+}{O}H_2$. For the protonated alcohol, the leaving group is H_2O instead of OH^-. Because H_2O is a much weaker base than OH^-, it is a much better leaving group. In reaction (27.5), the conditions are just right for an S_N2 reaction: the α carbon atom in $CH_3CH_2CH_2OH$ is primary (not sterically hindered) and I^- is a very good nucleophile. The mechanism of the reaction is shown in Figure 27-14. It involves a reversible protonation step followed by an S_N2 reaction. Recall that an S_N2 reaction is a concerted reaction involving backside attack at the α carbon.

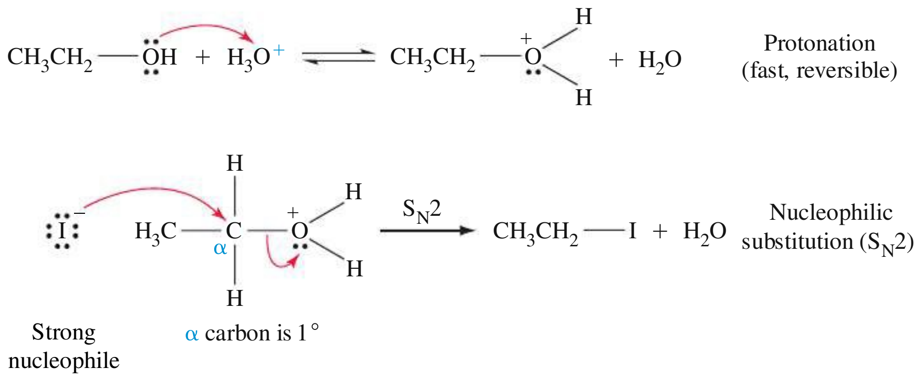
KEEP IN MIND

that the weaker the base, the better it is as a leaving group. I^- is a very weak base and a good leaving group. OH^- is a strong base and a poor leaving group.

27-3 CONCEPT ASSESSMENT

Draw the structure of the transition state for the second step shown in Figure 27-14.

If a tertiary alcohol, such as $(CH_3)_3COH$, is used in place of the primary alcohol in reaction (27.5), the substitution occurring in the second step occurs by an S_N1 reaction, not by S_N2. Substitution occurs by S_N1 because the backside of

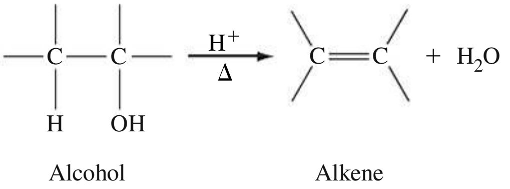


Protonation
(fast, reversible)
S_N2
Nucleophilic substitution (S_N2)
Strong nucleophile
α carbon is 1°

▲FIGURE 27-14
Mechanism for the reaction of CH_3CH_2OH and HI
The first step is a reversible step in which the oxygen atom of the alcohol functional group is protonated. The second step is a nucleophilic attack of the α carbon. Because the α carbon is primary and I^- is a strong nucleophile, the substitution occurs by the S_N2 mechanism.

the α carbon in a tertiary alcohol is sterically hindered and inaccessible to a nucleophile. As shown in Figure 27-15, the substitution involves the formation of a carbocation followed by nucleophilic attack by I^-. The carbocation is stabilized by the electron-donating alkyl groups.

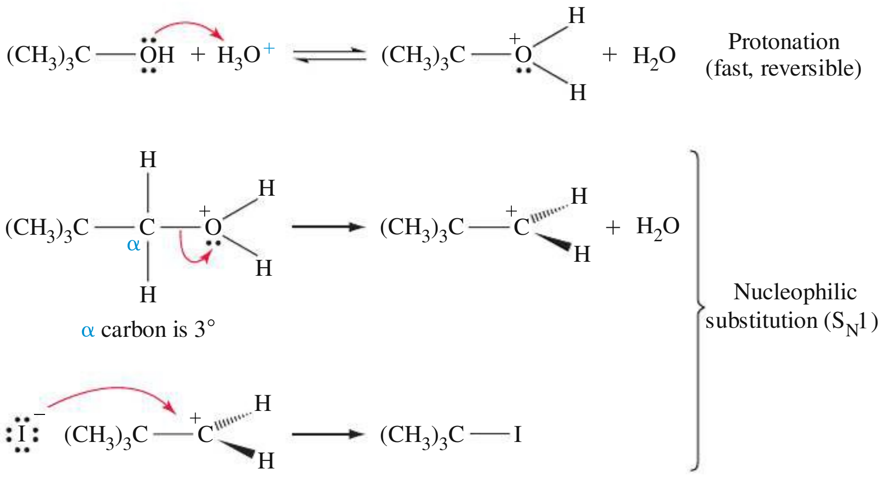
As we saw in the previous sections, elimination reactions compete with substitution reactions. So, it should come as no surprise that alcohols can also undergo elimination reactions. The elimination of water (H—OH) from an alcohol is an important method of synthesizing alkenes. The elimination of water from an alcohol is also called a **dehydration reaction**. The general form of a dehydration reaction is



H^+
Δ
Alcohol
Alkene

(27.6)

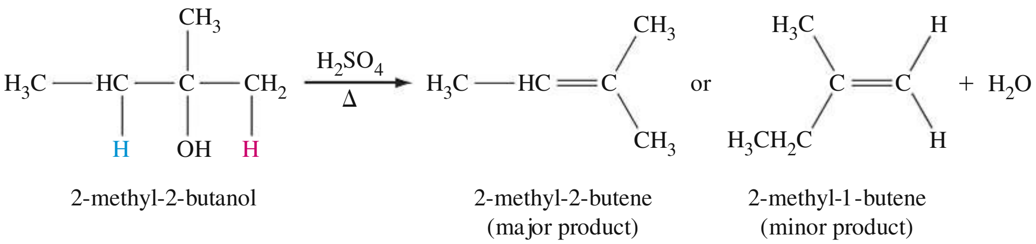
The dehydration of an alcohol requires an acid catalyst. The acid catalyst protonates the alcohol so that the leaving group will be H_2O (a good leaving group) rather than OH^- (a poor leaving group). To promote elimination (dehydration)



Protonation
(fast, reversible)
α carbon is 3°
Nucleophilic substitution (S_N1)

▶FIGURE 27-15
Mechanism for the reaction of $(CH_3)_3COH$ and HI
The first step is a reversible step in which the oxygen atom of the alcohol functional group is protonated. Because the α carbon is tertiary, the backside of the α carbon is not susceptible to backside attack and so substitution by S_N2 does not occur. Instead, substitution occurs by S_N1.

over substitution, concentrated H_2SO_4 or H_3PO_4 is used rather than HI or HBr. (Remember, I^- and Br^- are strong nucleophiles, and if HI or HBr is used in place of H_2SO_4 or H_3PO_4, substitution will dominate over elimination.) Dehydration of tertiary alcohols occurs by an E1 reaction. Consider, for example, the dehydration of 2-methyl-2-butanol, a tertiary alcohol:



H₂SO₄
Δ
or
+ H₂O
2-methyl-2-butanol
2-methyl-2-butene
(major product)
2-methyl-1-butene
(minor product)

The mechanism for this reaction is shown in Figure 27-16. The first step (Fig. 27-16a) involves protonation of the alcohol. After protonation, dehydration occurs by E1 (Fig. 27-16b). Elimination of H—OH yields 2-methyl-2-butene and elimination of HO—H yields 2-methyl-1-butene. As discussed in Section 27-3, the major product in an elimination reaction is usually the more highly substituted alkene.

KEEP IN MIND

that primary alcohols with bulkier structures, such as $(CH_3)_3CCH_2OH$ which has three methyl groups bonded to the β carbon atom, can undergo elimination by E1 because the electron-donating methyl groups on the β carbon help to stabilize the carbocation.

(a) Protonation of the alcohol

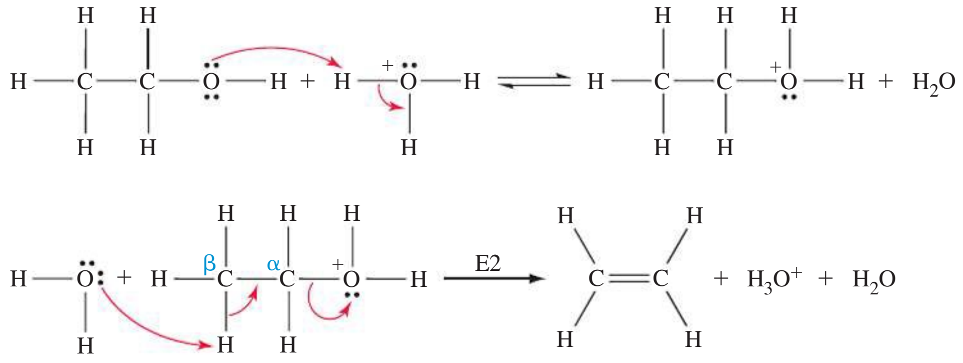
Minor elimination product

▲ FIGURE 27-16

Mechanism for the acid-catalyzed dehydration of 2-methyl-2-butanol

(a) In the presence of strong acid, the alcohol is protonated. **(b)** Elimination involves the formation of a carbocation, followed by the removal of a proton from one of the β carbons. The blue arrows show the movement of electrons when H is attacked. The red arrows show the movement of electrons when H is attacked. The major product is the more highly substituted alkene. Notice that the H_3O^+ ion consumed in the protonation step is regenerated in the last step.

Dehydration of secondary alcohols usually occurs by E1, but it can occur by E2. Ethanol, a primary alcohol, undergoes dehydration by a concerted E2 reaction, as shown below:



EXAMPLE 27-6 Predicting the Products of a Reaction Involving an Alcohol

Predict the products of the following reactions. If appropriate, suggest a mechanism by which the reaction occurs by using arrows to show the movement of electrons.

(a) 1-propanol + sodium hydroxide $\xrightarrow{H_2O}$

(b) (*R*)-2-bromo-3-methylbutane + ethanol $\xrightarrow{\text{ethanol}}$

Analyze

First, we write condensed structural formulas for the reactants, and then we consider the role of the alcohol in each case. Alcohols can be oxidized or deprotonated. They can act as either a nucleophile or an electrophile in a substitution reaction or they can be dehydrated. To make a decision, we must consider the α carbon atoms in the reactants and classify them as primary, secondary, or tertiary. We must also consider the other reactants, the solvent, and the reaction conditions.

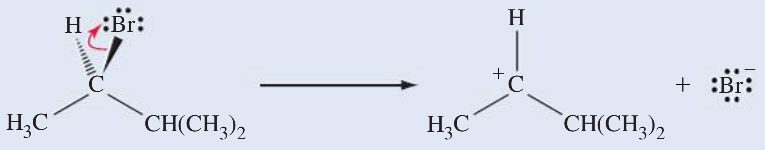
Solve

(a) The condensed structural formula for 1-propanol is $CH_3CH_2CH_2OH$. It is a primary alcohol. Neither substitution nor elimination (dehydration) is possible under the conditions specified. We know that sodium hydroxide is a relatively strong base, and so we should consider the feasibility of the following acid–base reaction:

$$CH_3CH_2CH_2OH + NaOH \longrightarrow CH_3CH_2CH_2O^-Na^+ + H_2O$$

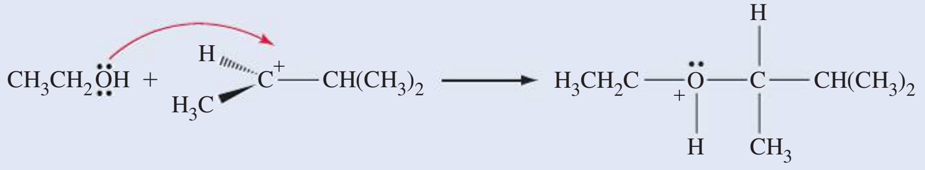
We must compare the strengths of the acids (or the bases) on either side of the equation. We know that ^-OH and $CH_3CH_2CH_2O^-$ are both considered strong bases, but which is stronger? Because both bases have the negative charge localized on oxygen, we expect them to be fairly similar in strength. Thus, we predict that the reaction will not go to completion. At equilibrium, significant amounts of all species will be present.

(b) The condensed structural formulas for 2-bromo-3-methylbutane and ethanol are $CH_3CHBrCH(CH_3)_2$ and CH_3CH_2OH. The carbon bonded to bromine in the haloalkane is a 2° carbon atom and Br^- is a very weak base and a good leaving group. CH_3CH_2OH is a weak base and also a weak nucleophile. The solvent is polar protic. On the basis of this information, we conclude that S_N1 and E1 reactions will occur (see Fig. 27-13). The first step in both the S_N1 and E1 mechanisms is the formation of the carbocation:

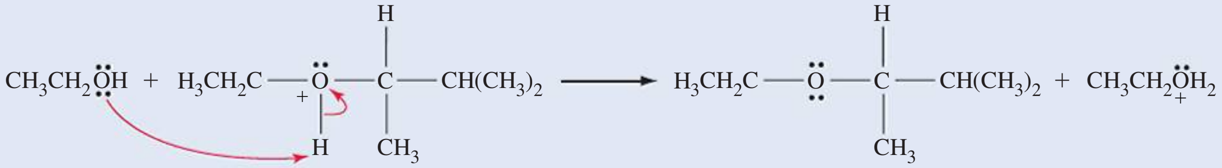


(*R*)-2-bromo-3-methylbutane

Once the carbocation is formed, either substitution or elimination can occur. The steps involved in the substitution are as follows:



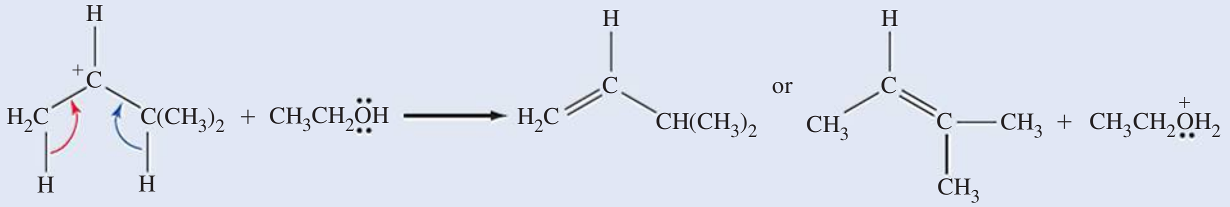
(*R*) and (*S*)



(*R*) and (*S*)

In the diagram above, the nucleophile is shown attacking the carbocation from above, but it can attack from either above or below. Consequently, both (*R*) and (*S*) stereoisomers are obtained.

The steps involved in the elimination are shown below. The elimination reaction produces two alkenes. The major product is the most highly substituted alkene.



3-methyl-1-butene (minor elimination product)

2-methyl-2-butene (major elimination product)

Assess

As shown in **(a)**, the deprotonation of CH_3CH_2OH cannot be accomplished effectively by using NaOH. However, the deprotonation can be accomplished by using $NaNH_2$. The pK_a for NH_3 is about 34, and so pK_b for NH_2^- is about $14 - 34 = -20$. For part **(b),** keep in mind that a carbocation can undergo a rearrangement (see Are You Wondering 27-2). Consequently, a variety of products are obtained in substitution and elimination reactions involving secondary and tertiary alcohols. We will not explore this complication.

PRACTICE EXAMPLE A: Predict the products of the following reactions. If appropriate, suggest a mechanism by which the reaction occurs, using arrows to show the movement of electrons.

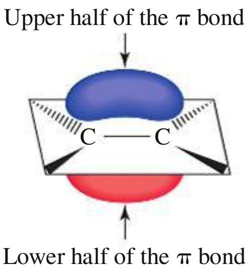
(a) (*R*)-2-butanol $\xrightarrow[H_2SO_4]{Na_2Cr_2O_7}$ **(b)** 1-propanol $\xrightarrow[\Delta]{\text{conc. } H_2SO_4}$

PRACTICE EXAMPLE B: Predict the products of the following reactions. If appropriate, suggest a mechanism by which the reaction occurs, using arrows to show the movement of electrons.

(a) 3-methyl-1-butanol + hydrogen iodide $\longrightarrow$ **(b)** 2-methyl-2-propanol + sodium $\longrightarrow$

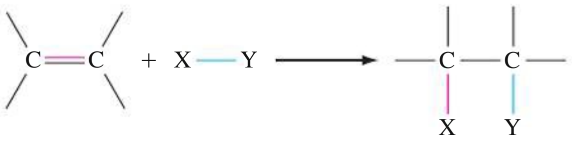
27-5 Introduction to Addition Reactions: Reactions of Alkenes

In the previous sections, we focused on reactions involving Lewis bases or nucleophiles in which the electron pair to be donated was a lone pair of electrons. In this section, we focus on a few reactions of alkenes, such as $(CH_3)_2C{=}CH_2$, and will see that the π bond in these molecules acts as the Lewis base or nucleophile in those reactions.



▲ FIGURE 27-17
Schematic representation of the π bond in an alkene
Each of the two carbon atoms is sp^2 hybridized and forms three σ bonds. The σ bonds are shown by using the dashed-wedge and solid-wedge notation. The π bond in an alkene places electron density above and below the plane of the atoms bonded to the carbon atoms by σ bonds.

The characteristic reaction of alkenes (and alkynes) is addition of two substituents, X and Y, to each of the carbons in the double or triple bond. In this section, we will focus primarily on addition reactions of alkenes. The general equation for the addition of X—Y to an alkene is shown below.



(27.7)

The region of reactivity in an alkene is the π bond. As illustrated in Figure 27-17, the π bond between the two carbons in an alkene places a high electron charge density above and below the plane of the atoms bonded to the sp^2-hybridized carbon atoms. The electrons in the π bond are not as tightly held as the electrons in the σ bonds, and they are drawn toward electrophilic atoms. The transfer of electron density from the π bond of an alkene to an electrophile is a common feature in the reactions we discuss in this section.

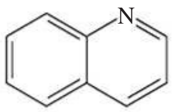
Addition of Hydrogen: Hydrogenation

The addition of H_2 across the double bond of an alkene yields an alkane. The reaction is very slow unless a finely divided metal catalyst, such as Ni, Pd, Pt, or Rh, is used. The equation for the hydrogenation of propene, $CH_3CH{=}CH_2$, by using Pt metal as a catalyst is given below:

$$CH_2{=}CH_2 + H_2 \xrightarrow{Pt} CH_3CH_3$$

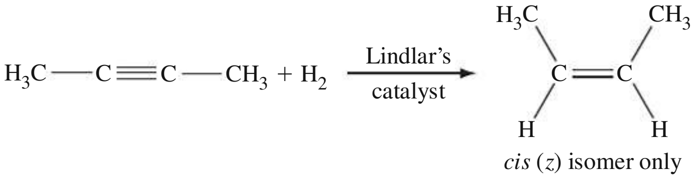
A schematic representation of the mechanism of this reaction was shown in Chapter 23 (Fig. 23-3). Catalytic hydrogenation of alkenes is an important industrial process. For the purposes of synthesizing other organic compounds, other reactions of alkenes are more useful.

The hydrogenation of alkynes is similar to that for alkenes. The metal-catalyzed hydrogenation of an alkyne also yields an alkane, unless a special catalyst called Lindlar's catalyst is used. Lindlar's catalyst consists of barium sulfate coated with palladium metal and "poisoned" with quinoline, a heterocyclic aromatic compound shown in the margin. In Lindlar's catalyst, the catalytic activity of palladium is decreased and the hydrogenation of an alkyne stops at the alkene. The chemical equations are given below for the hydrogenation of 2-butyne by using Pt as a catalyst and Lindlar's catalyst. Notice that when a "pure" metal catalyst is used, the hydrogenation of an alkyne consumes two moles of hydrogen per mole of alkyne. When Lindlar's catalyst is used, only the *cis* (*Z*) stereoisomer is obtained. The two H atoms add from the same side.



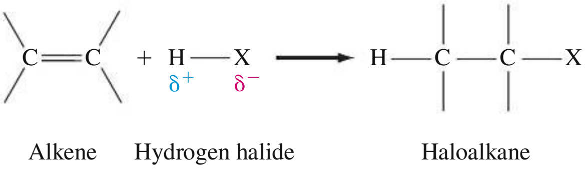
▲ Quinoline is used in Lindlar's catalyst to lower the catalytic activity of palladium metal.

$$H_3C{-}C{\equiv}C{-}CH_3 + 2\,H_2 \xrightarrow{Pt} CH_3CH_2CH_2CH_3$$

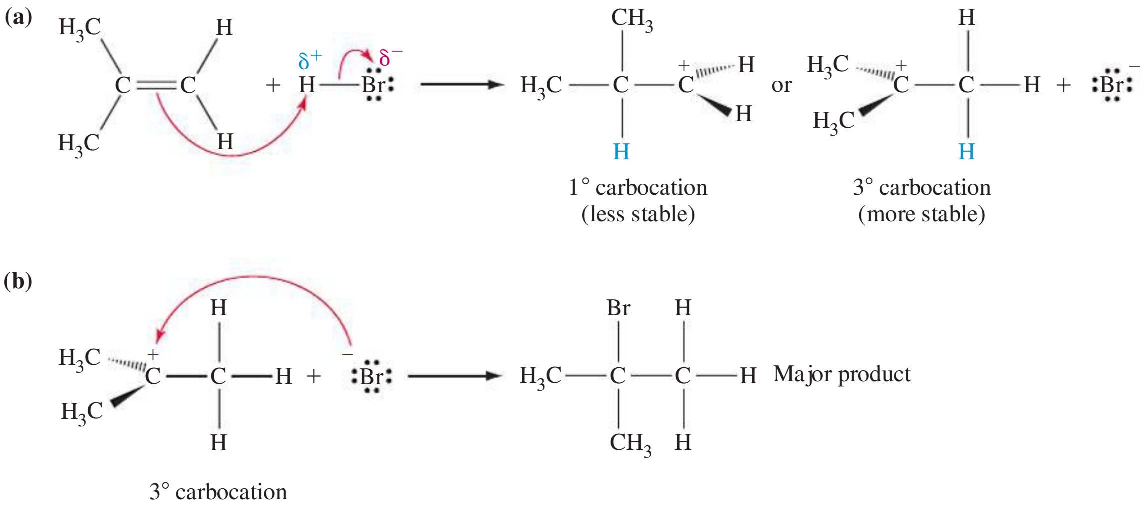


Addition of Hydrogen Halides (HX)

The addition of HX to an alkene can be represented by the following general equation:



(27.8)



▲ FIGURE 27-18

Mechanism for electrophilic addition of HBr to 2-methyl-1-propene

(a) The alkene acts a nucleophile and attacks the partially positive hydrogen atom of HBr. In principle, the H atom can add to either carbon atom of the double bond, but there is a strong preference for adding to the least-substituted carbon atom. When H adds to the least substituted carbon atom, the resulting carbocation is more stable.

(b) The Br^- ion attacks the positive carbon atom of the carbocation.

The mechanism for the reaction consists of two steps, as illustrated in Figure 27-18 for the reaction of $(CH_3)_2C{=}CH_2$ and HBr.

In the first step (Fig. 27-18a), the partially positive H atom adds to one of the carbon atoms of the double bond. This step produces a carbocation. In principle, the H atom can add to either one of the carbon atoms but, in practice, it adds preferentially to the least-substituted carbon atom. When H adds to the least substituted carbon, the positive charge of the carbocation ends up on the carbon atom most able to stabilize the positive charge, that is, on the most highly substituted carbon. (Recall that alkyl groups help to stabilize a carbocation.) In the second step (Fig. 27-18b), the Br^- ion acts as a nucleophile and attacks the positively charged carbon atom of the carbocation.

When H—X adds to the double bond of an alkene, the H atom adds to the carbon atom having the smallest number of alkyl groups.

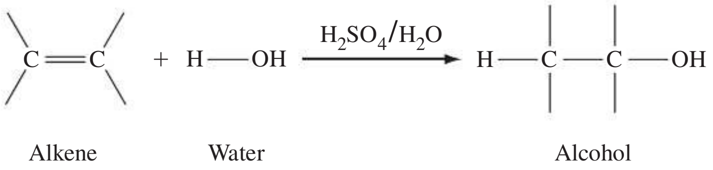
If the reaction is carried out in an aqueous solution, a mixture of products is obtained. To avoid this complication, the reaction can be carried out by bubbling HCl, HBr, or HI through the pure alkene or by carrying out the reaction in a solvent whose molecules are not nucleophilic.

27-4 CONCEPT ASSESSMENT

What are the major and minor products obtained in the reaction of (*E*)-3-methyl-2-pentene and HBr?

Addition of Water: Hydration

The addition of H_2O to an alkene is represented by the following general equation. An alcohol is formed.

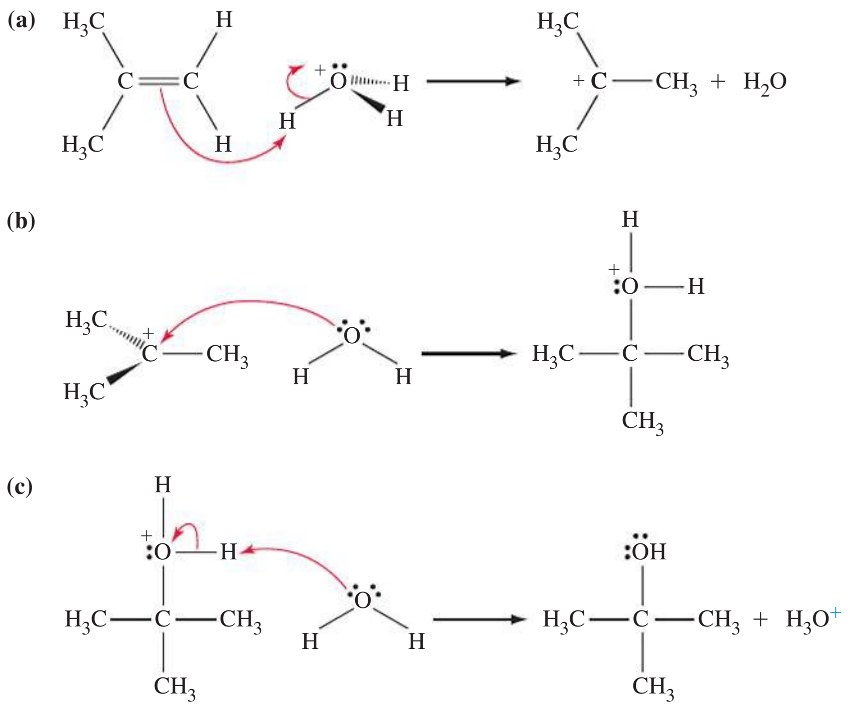


(27.9)

The reaction occurs only in an acid solution and can be carried out in a mixture of H_2SO_4 and H_2O (typically 50% H_2SO_4 by volume). The mechanism is similar to the one given previously for the addition of HX to an alkene. It involves the formation of a carbocation followed by nucleophilic attack. The mechanism for the reaction of $(CH_3)_2C{=}CH_2$ and H_2O is shown in Figure 27-19. In an acidic solution, there is an excess of H_3O^+ ions, and these ions are the source of the electrophile, H^+. In the first step, an H atom from H_3O^+ adds to the carbon that has the fewest number of H atoms, yielding a carbocation (Fig. 27-19a). In the second step, a water molecule acts as a nucleophile and attacks the positively charged carbon of the carbocation (Fig. 27-19b). In the third step, a proton is removed, yielding an alcohol (Fig. 27-19c).

27-5 CONCEPT ASSESSMENT

Would hydration of (*E*)-2-butene yield exclusively (*R*)-2-butanol, (*S*)-2-butanol, or a mixture of the (*R*) and (*S*) enantiomers? Explain.

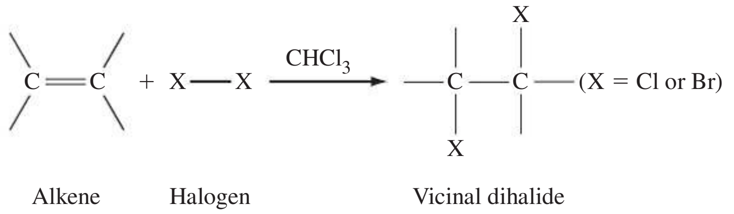


▶ FIGURE 27-19
Mechanism for the acid-catalyzed addition of H_2O to 2-methyl-1-propene
(a) In an acidic solution, an H atom from an H_3O^+ ion can add to a carbon in the double bond of an alkene. As discussed in the text, there is a preference for the H atom to add to the least-substituted carbon atom. The other carbocation that can be formed in this step is less stable and is not shown.
(b) A water molecule attacks the carbocation, forming a protonated alcohol.
(c) The protonated alcohol transfers a proton to a water molecule.

Addition of Halogens: Halogenation

When a halogen, represented by X_2, adds across the double bond of an alkene, the product is a dihalide. The halogen atoms are bonded to adjacent carbons. Such a dihalide is called a **vicinal dihalide**. (When two halogen atoms are bonded to the same carbon, the compound is a **geminal**

dihalide.) The general equation for the addition of X_2 to an alkene is shown in equation (27.10):



(27.10)

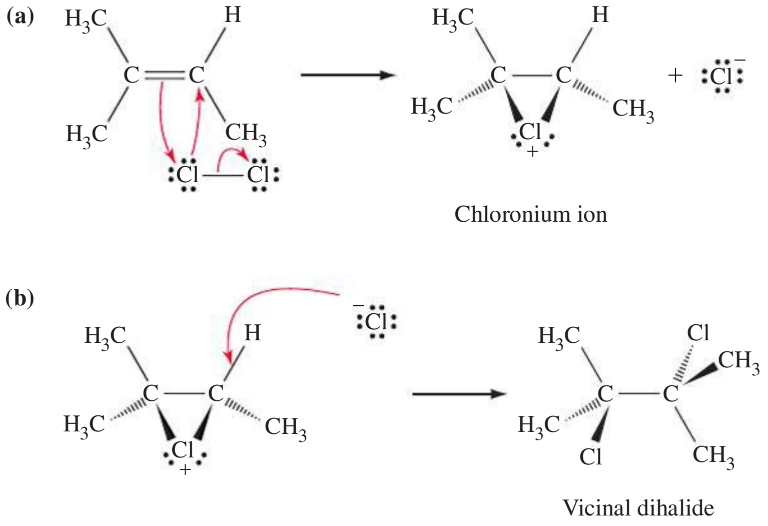
The reaction above occurs readily at room temperature when the halogen is Cl_2 or Br_2. A nonaqueous solvent, such as $CHCl_3$ or CCl_4, must be used to prevent the formation of other products, including alcohols. The mechanism for the addition of X_2 to an alkene is significantly different from the mechanisms considered previously for the addition of HX and H_2O. The first step of the mechanism is the formation of a **bridged halonium ion**, rather than a carbocation (Fig. 27-20a). In the halonium ion, the halogen atom is bonded to two carbon atoms and it is the atom that carries the positive charge. Notice that the carbon atoms and the halogen atom in the halonium ion all have complete octets. Take careful note of the movement of electrons that occurs in the formation of the halonium ion. The electron pair in the π bond of the alkene is directed toward a chlorine atom. As this occurs, an electron pair from a chlorine atom is directed toward one of the carbon atoms and the Cl—Cl bond is breaking. In the next step (Fig. 27-20b), a Cl^- ion attacks a carbon atom in the bridge from the backside because the bridge blocks the carbon atoms from a frontside attack.

27-6 CONCEPT ASSESSMENT

Apply the ideas discussed above to the bromination of cyclopentene. What is the product obtained in this reaction? Specify stereochemistry, if relevant.

Carboxylic acids and their derivatives are important organic compounds. They are found widely in nature, and biological systems, and are used extensively in organic synthesis. The reactions of these compounds, and the mechanisms by which they occur, are discussed in Section 27C, *Carboxylic Acids and Their Derivatives: The Addition-Elimination Mechanism*, on the MasteringChemistry site (www.masteringchemistry.com).

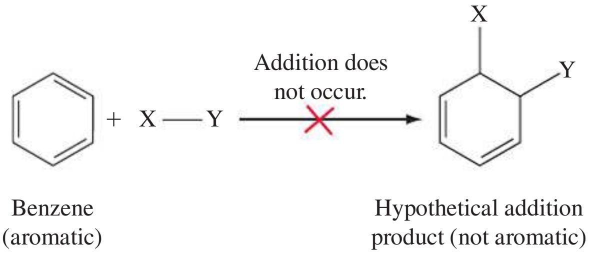
MasteringCHEMISTRY



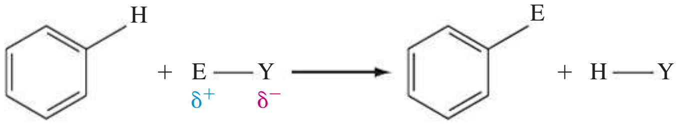
◀ FIGURE 27-20 **Mechanism for chlorination of 2-methyl-1-propene** **(a)** A chlorine atom adds to the alkene by bonding simultaneously to both carbon atoms of the double bond. The structure formed in this step is called a chloronium ion. Notice that the chlorine atom bridges two carbon atoms and is the atom carrying the positive charge. **(b)** In the second step, a Cl^- attacks one of the carbon atoms in the bridge from the backside. A vicinal dihalide is formed.

27-6 Electrophilic Aromatic Substitution

We saw in the previous section that alkenes typically undergo addition reactions, in which substituents add across a carbon–carbon double bond. Because we often represent the structure of benzene as a six-membered ring with alternating single and double bonds, it is tempting to think that benzene would also undergo addition reactions in which substituents add across one of the carbon–carbon double bonds. As illustrated below, benzene does not undergo addition reactions:



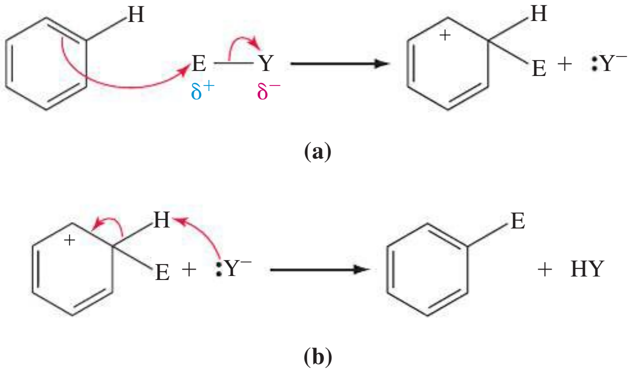
Benzene and its derivatives typically react with electrophiles in substitution reactions. The general equation for the reaction of benzene and an electrophilic species, E—Y, is shown below:



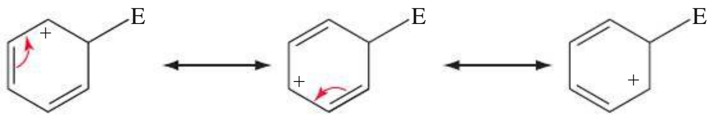
(27.11)

The reaction is an **electrophilic substitution reaction** because one of the hydrogen atoms in benzene is replaced by, or substituted with, an electrophile, E. The mechanism is shown Figure 27-21 and it involves two steps. In the first step, the electrophile accepts an electron pair from the π system of the benzene ring to form a carbocation, $C_6H_6E^+$, called an **arenium ion**. In the second step, the arenium ion loses a proton. In essence, electrophilic aromatic substitution follows an addition-elimination sequence. Notice that in the second step, Y^- acts as a base and attacks the H atom on the carbon that is bonded to E. It is tempting (but wrong) to think that Y^- would act as a nucleophile and attack the positively charged carbon atom of the arenium ion. Y^- does not attack the positively charged carbon for two reasons. First, the positive charge of the arenium ion is not localized on a particular carbon atom. It is shared equally by three carbons, as suggested in Figure 27-22, and thus these carbon atoms are only partially positive. Second, and more important, if Y^- attacks and forms a bond with one of the partially positive carbon atoms, the resulting product is not aromatic and thus is much less stable.

Various electrophilic aromatic substitutions are possible, each of which involves a different electrophilic species. We will examine a few cases, placing special consideration on the methods used for generating the electrophile.



▶ FIGURE 27-21
General mechanism for electrophilic aromatic substitution of benzene
(a) The electrophile accepts an electron pair and forms a bond with a carbon atom in the benzene ring. The aromaticity of the ring is lost. **(b)** A proton is removed from the carbocation, restoring the aromaticity of the ring.



▲ FIGURE 27-22

Three equivalent contributing structures for $C_6H_6E^+$

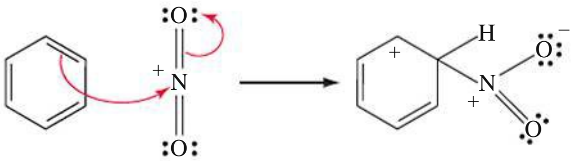
There are three equivalent contributing structures for the $C_6H_6E^+$ carbocation. The positive charge is shared equally by three carbon atoms in the ring.

Nitration: Substitution of —H with —NO_2

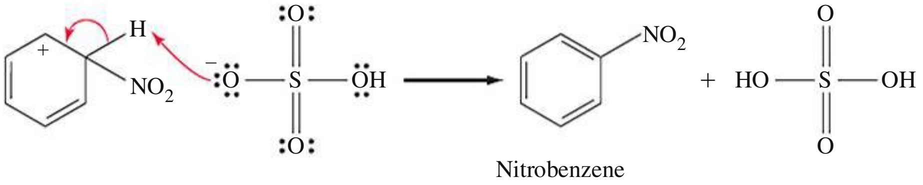
To replace an H atom in benzene with a nitro group, —NO_2, benzene is treated with a mixture of sulfuric acid (H_2SO_4) and nitric acids (HNO_3). The reaction of H_2SO_4 and HNO_3 produces a nitronium ion, NO_2^+:

$$HNO_3 + 2\,H_2SO_4 \longrightarrow O{=}N^+{=}O + H_3O^+ + 2\,HSO_4^-$$

The mechanism for the nitration of benzene involves two steps. In the first step, the nitrogen atom of the nitronium ion accepts a pair of electrons from the π system of the benzene ring. A carbon–nitrogen bond is formed:

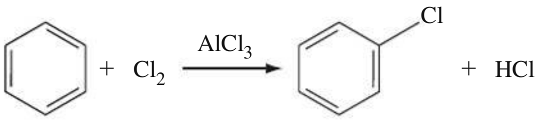


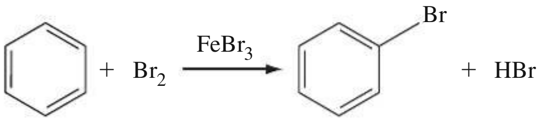
In the second step, the arenium ion is deprotonated by HSO_4^-, yielding nitrobenzene:



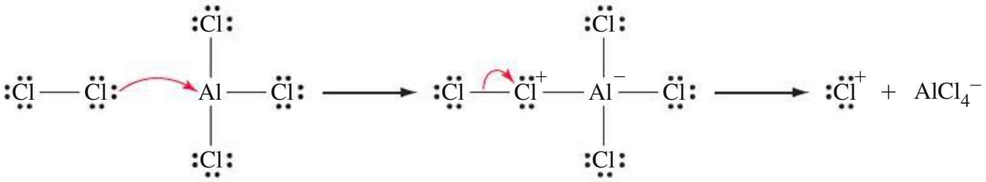
Halogenation

Benzene can be converted into chlorobenzene or bromobenzene by treating benzene with either Cl_2 or Br_2 in the presence of an appropriate catalyst. The chemical equations for these conversions are shown below:

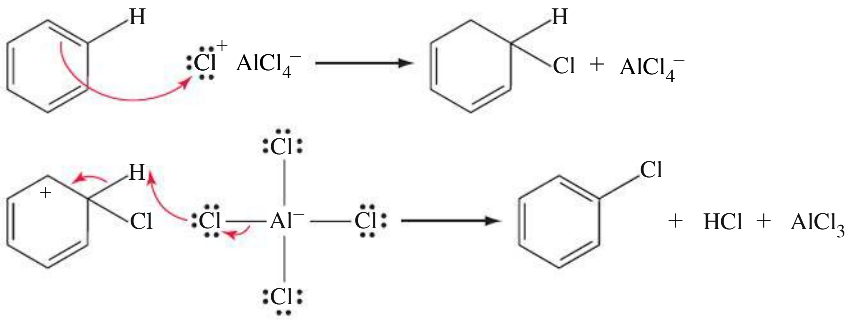


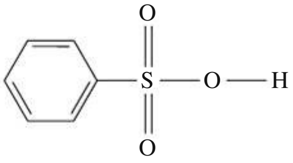


In these reactions, the catalyst reacts with Cl_2 or Br_2 to form an intermediate species that reacts with benzene. For example, Cl_2 and $AlCl_3$ react as follows:



Following the formation of $Cl^+AlCl_4^-$, the chlorination of benzene proceeds as follows.



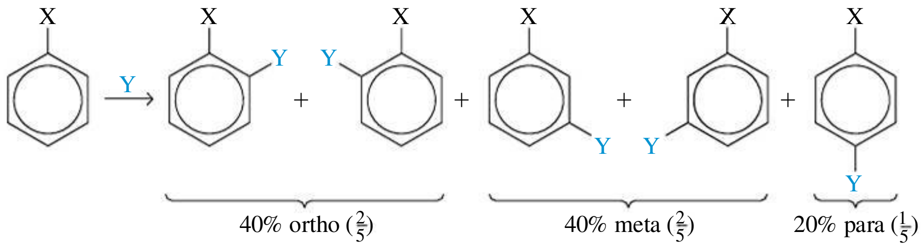


Benzenesulfonic acid

Many other substitutions are possible. For example, treating benzene with either concentrated sulfuric acid or *fuming sulfuric acid* (SO_3 in concentrated H_2SO_4) replaces a hydrogen atom with the $—SO_3H$ group to make benzenesulfonic acid (see Exercise 37). Methods and reagents are available for replacing an H atom with an alkyl group, R (see Exercise 38), or an acyl group, RC═O.

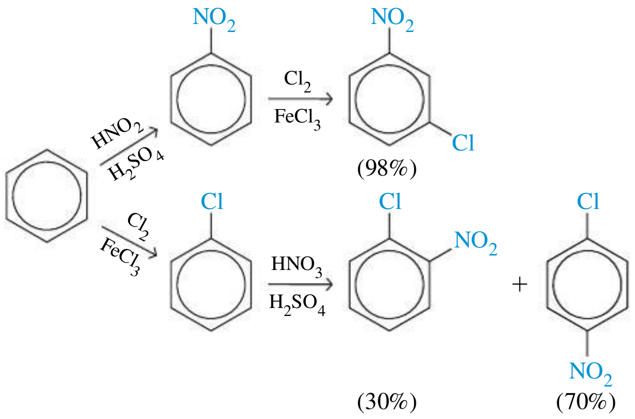
Ortho, Para-directing Substituents and Meta-directing Substituents

The substitution of a single atom or group, X, for an H atom in benzene can occur at any one of the six positions on the ring. We say that the six positions are equivalent. If a group Y is substituted for an H atom in C_6H_5X, this question arises: To which of the remaining five positions does the Y group go? If all the sites on the benzene ring were equally preferred, the distribution of the products would be a purely statistical one. That is, Y can be substituted in five possible positions, and we should get 20% of each one. Since two possibilities lead to an *ortho* isomer and two lead to a *meta* isomer, however, we should expect the distribution of products to be 40% ortho, 40% meta, and 20% para:



▲ A Chinese rose has the aroma of black tea, primarily because of 1,3-dimethoxy-5-methylbenzene, a derivative of benzene.

The following scheme describes the products resulting from nitration followed by chlorination (reaction 27.10) and chlorination followed by nitration (reaction 27.11). It shows that the substitution is *not random*. The $—NO_2$ group directs Cl to a meta position. Almost no *ortho* or *para* isomer is formed in reaction (27.12). The Cl group, on the other hand, is an *ortho*, *para* director. Essentially no *meta* isomer is produced in reaction (27.13).



(27.12)

(27.13)

Whether a group is an *ortho*, *para*, or *meta* director depends on how the presence of one substituent alters the electron distribution in the benzene ring. As a result, attack by a second group is more likely at one type of position than another. Examination of many reactions leads to the following order:

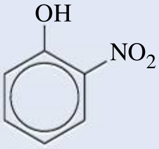
Ortho, *para directors*: —NH_2, —OR, —OH, —OCOR, —R, —X (X = halogen) (from strongest to weakest)

Meta directors: —NO_2, —CN, —SO_3H, —CHO, —COR, —COOH, —COOR (from strongest to weakest)

When two groups of the same type (both *o*-, *p*-directing or both *m*-directing) are present, the stronger director wins out. When two groups of different type (one *o*-, *p*-directing and one *m*-directing) are present, then the *o*-, *p*-directing group guides the reaction.

EXAMPLE 27-7 Predicting the Products of an Aromatic Substitution Reaction

Predict the products of the mononitration of

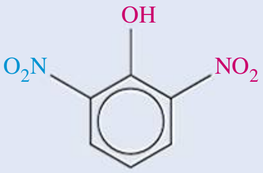


Analyze

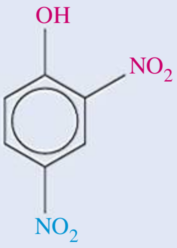
The groups are different, and so the *o*-, *p*-directing group (—OH) guides the reaction.

Solve

Because the —OH group is an *o*-, *p*-directing group and guides the reaction, we expect the following products:



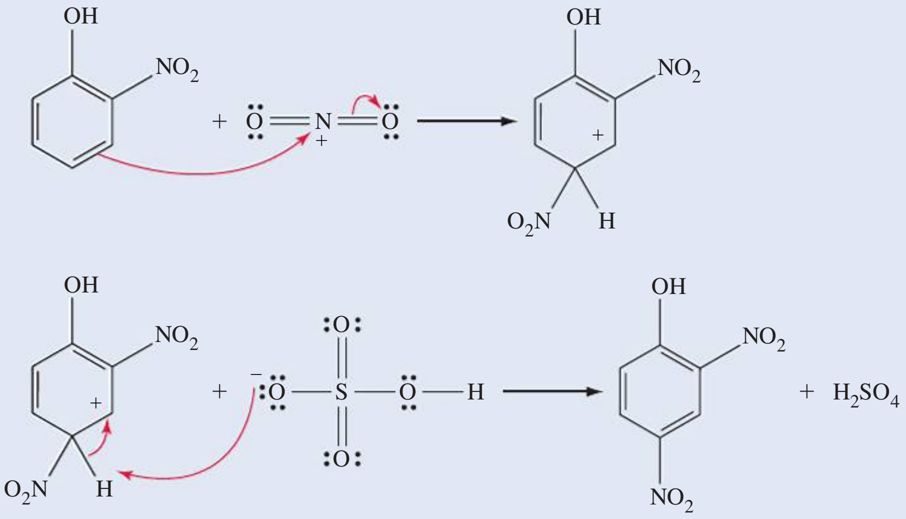
2,6-dinitrophenol



2,4-dinitrophenol

Assess

In the diagrams below, we show the flow of electron density that occurs during the formation of 2,4-dinitrophenol:



PRACTICE EXAMPLE A: Predict the major product(s) of the mononitration of benzaldehyde, C_6H_5CHO.

PRACTICE EXAMPLE B: Predict the major product(s) of the mononitration of 1,3-dichlorobenzene.

27-7 Reactions of Alkanes

Saturated hydrocarbons have little affinity for most chemical reactants. They are nonpolar substances that are insoluble in water and unreactive toward acids, bases, or oxidizing agents. The most commonly encountered reaction of alkanes is with oxygen. Alkanes burn; the *oxidation* of hydrocarbons underlies their important use as fuels. For example, octane reacts with oxygen as follows:

$$\mathrm{C_8H_{18}(l)} + \frac{25}{2}\mathrm{O_2(g)} \longrightarrow 8\,\mathrm{CO_2(g)} + 9\,\mathrm{H_2O(l)} \qquad \Delta H^\circ = -5.48 \times 10^3\ \mathrm{kJ} \tag{27.14}$$

Alkanes, however, will also react with halogens under the right conditions. For example, alkanes react only slowly with halogens at room temperature, but at higher temperatures, particularly in the presence of light, halogenation occurs. The reaction between an alkane and a halogen is a substitution reaction, with the halogen atom replacing a hydrogen atom. For example, in the reaction below, a chlorine atom replaces a hydrogen atom in methane:

$$\mathrm{CH_4} + \mathrm{Cl_2} \xrightarrow[\text{light}]{\text{heat or}} \mathrm{CH_3Cl} + \mathrm{HCl} \tag{27.15}$$

The substitution occurs by a *chain reaction*, written as follows for the chlorination of methane. (Only the electrons involved in bond breakage or formation are shown.)

$$\begin{array}{lrcl}
\textit{Initiation:} & \mathrm{Cl}{:}\mathrm{Cl} & \xrightarrow[\text{light}]{\text{heat or}} & 2\,\mathrm{Cl}\cdot \\[1ex]
\textit{Propagation:} & \mathrm{H_3C}{:}\mathrm{H} + \mathrm{Cl}\cdot & \longrightarrow & \mathrm{H_3C}\cdot + \mathrm{H}{:}\mathrm{Cl} \\
 & \mathrm{H_3C}\cdot + \mathrm{Cl}{:}\mathrm{Cl} & \longrightarrow & \mathrm{H_3C}{:}\mathrm{Cl} + \mathrm{Cl}\cdot \\[1ex]
\textit{Termination:} & \mathrm{Cl}\cdot + \mathrm{Cl}\cdot & \longrightarrow & \mathrm{Cl}{:}\mathrm{Cl} \\
 & \mathrm{H_3C}\cdot + \mathrm{Cl}\cdot & \longrightarrow & \mathrm{H_3C}{:}\mathrm{Cl} \\
 & \mathrm{H_3C}\cdot + \mathrm{H_3C}\cdot & \longrightarrow & \mathrm{H_3C}{:}\mathrm{CH_3}
\end{array}$$

The reaction is initiated when some $\mathrm{Cl_2}$ molecules absorb sufficient energy to dissociate into Cl atoms (represented above as $\mathrm{Cl}\cdot$). Cl atoms collide with $\mathrm{CH_4}$ molecules to produce methyl *free radicals* ($\mathrm{H_3C}\cdot$), which combine with $\mathrm{Cl_2}$ molecules to form $\mathrm{CH_3Cl}$ molecules. When any or all of the last three reactions proceed to the extent of consuming the free radicals present, the reaction stops. The initiation step occurs much less frequently than the propagation steps. For example, the dissociation of a single $\mathrm{Cl_2}$ molecule probably produces thousands of chlorination reactions.

In the chlorination of methane, a mixture of products, not just $\mathrm{CH_3Cl}$, is obtained. For example, $\mathrm{H_3C}\cdot$ radicals can combine to form $\mathrm{CH_3CH_3}$ molecules. Also, because a Cl atom is rather reactive, it can remove a hydrogen atom from any hydrogen-containing molecule in the system. If a Cl atom removes a hydrogen atom from a $\mathrm{CH_3Cl}$ molecule, an $\mathrm{H_2ClC}\cdot$ radical will be produced. A $\mathrm{H_2ClC}\cdot$ radical can then react with a $\mathrm{Cl_2}$ molecule or a Cl atom to give dichloromethane, $\mathrm{CH_2Cl_2}$ (methylene chloride, a solvent and paint remover). More highly halogenated products, including trichloromethane (chloroform, a solvent and fumigant), and tetrachloromethane (carbon tetrachloride, a solvent) will also be formed.

27-7 CONCEPT ASSESSMENT

In the chlorination of methane, small amounts of chloroethane will also be produced. Suggest how the formation of chloroethane might occur.

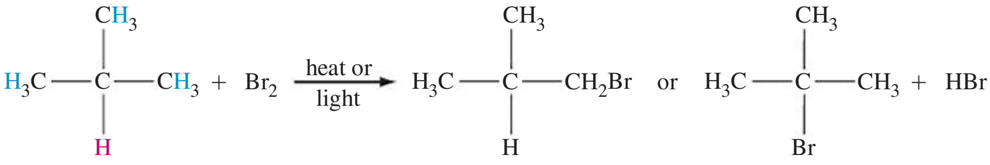
Not all the halogens show the same reactivity with methane. Iodine is not very reactive and fluorine reacts explosively with methane unless special precautions are taken.

$$\underset{\text{Increasing reactivity toward CH}_4}{\xrightarrow{\quad I_2 \ll Br_2 < Cl_2 \ll F_2 \quad}}$$

How can we rationalize this trend in reactivities? Let's compare the energy changes involved in the propagation steps (Table 27.4).

The activation energy for hydrogen removal is rather small for fluorine (only 5 kJ/mol) and quite large for iodine (140 kJ mol^{-1}). Thus, the rate of hydrogen removal is highest for fluorine and lowest for iodine. However, activation energies don't tell the whole story. The enthalpy change for the halogenation process also plays a role. For example, heat released by the propagation steps is not immediately dissipated to the surroundings and is absorbed by the reacting system, causing the temperature to rise. The greater the amount of heat released, the greater the temperature rise and the greater the increase in the rate of halogenation. For the fluorination of methane, the propagation steps release a large quantity of heat ($\Delta H° = -432$ kJ mol^{-1}), leading ultimately to a large increase in the rate of halogenation, whereas in the iodination of methane, the propagation steps absorb heat.

Just as the halogens show different reactivities, so too do the hydrogen atoms in a molecule. Consider, for example, the bromination of methylpropane:



$$H_3C-\underset{H}{\overset{CH_3}{C}}-CH_3 + Br_2 \xrightarrow[\text{light}]{\text{heat or}} H_3C-\underset{H}{\overset{CH_3}{C}}-CH_2Br \;\text{ or }\; H_3C-\underset{Br}{\overset{CH_3}{C}}-CH_3 + HBr$$

Methylpropane

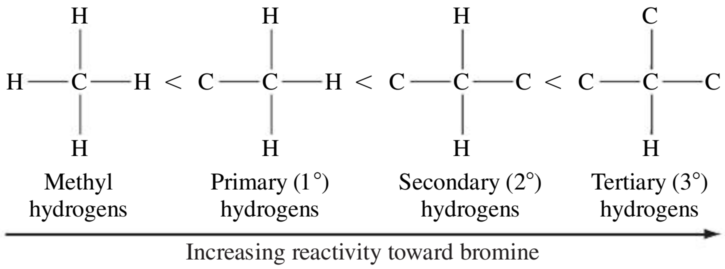
1-bromo-2-methylpropane (<1%)

2-bromo-2-methylpropane (>99%)

Methylpropane has two types of H atoms. The H atoms shown in blue are primary H atoms (see Figure 26-4) and the H atom shown in red is a tertiary H atom. From a statistical standpoint, we should expect 1-bromo-2-methylproprane to be the major product. (There are nine primary H atoms but only one tertiary H atom.) However, the major product is the one formed when the tertiary H atom is replaced. The selectivity of bromine for different H atoms is summarized on the next page. (Chlorine is more reactive and not as selective as bromine.)

TABLE 27.4 Activation Energy and Enthalpy Change Involved in the Halogenation of Methane

	Fluorination		Chlorination		Bromination		Iodination	
	E_a	$\Delta H°$	E_a	$\Delta H°$	E_a	$\Delta H°$	E_a	$\Delta H°$
$CH_4 + X\bullet \longrightarrow CH_3\bullet + HX$	5.0	−130	16	8	78	74	140	142
$CH_3\bullet + X_2 \longrightarrow CH_3X + X\bullet$	≈0	−302	≈0	−109	≈0	−100	≈0	−89
$CH_4 + X_2 \longrightarrow CH_3X + HX$		−432		−101		−26		53



The trend in reactivities can be rationalized in terms of the stabilities of the radicals that are formed when a particular H atom is removed. For example, the removal of a tertiary H atom yields a 3° radical, whereas the removal of a primary H atom yields a 1° radical. Like carbocations, radicals are stabilized by alkyl groups, and so the relative stabilities of radicals follow those of carbocations: 3° $>$ 2° $>$ 1° $>$ methyl.

27-8 CONCEPT ASSESSMENT

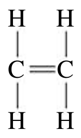
What is the major product obtained in the bromination of $(CH_3)_2CHCH_2CH_3$?

27-8 Polymers and Polymerization Reactions

An Overview

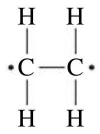
Polymers are made up of simple molecules with low molecular masses joined together into extremely large molecules. Polymers with molecular masses below about 20,000 u are called low polymers and those above 20,000 u are called high polymers.

One familiar polymer is *polyethylene*. As its name implies, its basic unit, or *monomer*, is the ethylene molecule, which has the Lewis structure



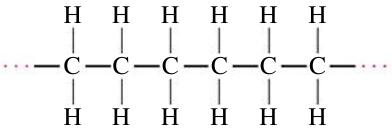
$$\begin{array}{ccc} H & & H \\ | & & | \\ C & = & C \\ | & & | \\ H & & H \end{array}$$

We can imagine that the polymerization of ethylene begins with the "opening up" of the double bonds in ethylene molecules.



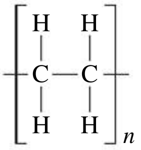
$$\begin{array}{ccc} H & & H \\ | & & | \\ \cdot C & - & C\cdot \\ | & & | \\ H & & H \end{array}$$

Then each C atom in the resulting molecular fragment (radical) forms an additional single covalent bond with a C atom in another molecular fragment, and so on, producing the structure shown below:



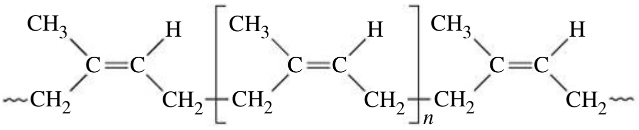
$$\begin{array}{ccccccccccccc} & H & & H & & H & & H & & H & & H & \\ & | & & | & & | & & | & & | & & | & \\ \cdots - & C & - & C & - & C & - & C & - & C & - & C & - \cdots \\ & | & & | & & | & & | & & | & & | & \\ & H & & H & & H & & H & & H & & H & \end{array}$$

In the following notation, the monomer unit is enclosed in square brackets and the subscript n signifies the number of monomers present in the final *macromolecule*. Typically, n might range from several hundred to several thousand.



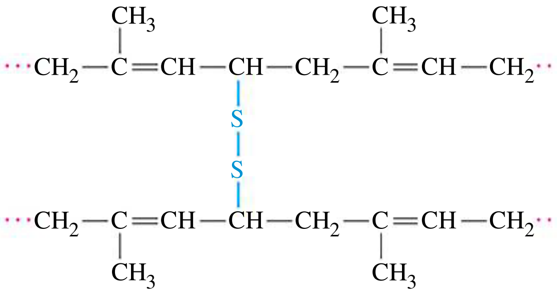
$$-\left[\begin{matrix} H & & H \\ | & & | \\ C & - & C \\ | & & | \\ H & & H \end{matrix}\right]_n-$$

Another polymer in which monomer units join end to end is *latex*—natural rubber:



Rubber

Early rubber products were of limited use because they were sticky in hot weather and stiff in cold weather. In 1839, Charles Goodyear accidentally discovered that by heating a sulfur–rubber mixture, a product could be made that was stronger, more elastic, and more resistant to heat and cold than natural rubber. This process is now called vulcanization (after *Vulcan*, the Roman god of fire). The purpose of vulcanization is to form *cross-links* between long polymer chains. An example of a cross-link through two sulfur atoms is shown here:



$$\begin{array}{ccccccccccccccc}
 & & CH_3 & & & & & & & & CH_3 & & & & \\
 & & | & & & & & & & & | & & & & \\
\cdots CH_2 & - & C & = & CH & - & CH & - & CH_2 & - & C & = & CH & - & CH_2\cdots \\
 & & & & & & | & & & & & & & & \\
 & & & & & & S & & & & & & & & \\
 & & & & & & | & & & & & & & & \\
 & & & & & & S & & & & & & & & \\
 & & & & & & | & & & & & & & & \\
\cdots CH_2 & - & C & = & CH & - & CH & - & CH_2 & - & C & = & CH & - & CH_2\cdots \\
 & & | & & & & & & & & | & & & & \\
 & & CH_3 & & & & & & & & CH_3 & & & &
\end{array}$$

Polymers are familiar products in the modern world. Nylon, one of the first polymers developed, is like an artificial silk and is used in making clothing, ropes, and sails. The fluorine-containing polymer Teflon (polytetrafluoroethylene) is used in nonstick frying and baking pans. Polyvinyl chloride (PVC) is used in food wrap, hoses, pipes, and floor tile. In all, the polymer industry is huge. It has been estimated that about half of all chemists work with polymers. Of particular interest to them are the reactions that can be used to make polymers. We will briefly survey the main types of polymerization reactions.

Chain-Reaction Polymerization

Monomers with carbon-to-carbon double bonds typically undergo **chain-reaction polymerization**. The net result is that the double bonds open up and monomer units add to growing chains. As with other chain reactions, the mechanism involves three characteristic steps: initiation, propagation, and termination. Let us illustrate this mechanism for the formation of the polymer polyethylene from the monomer ethylene (ethene). The key to the polymerization reaction is the free-radical initiator. In reaction (27.16), an organic peroxide dissociates into two peroxy radicals. The radicals add to the double bonds of ethylene molecules to form radical intermediates that attack more ethylene molecules and form new

◀ Molecules of a *poly*mer are formed by the joining together of many simple molecules called *mono*mers.

▲ Extruding polyethylene film.

intermediates of longer and longer length, as in reaction (27.17). The chains terminate as a result of reactions such as (27.18) and (27.19).

Initiation:

$$\underset{\text{an organic peroxide}}{R{-}O{:}O{-}R} \longrightarrow 2\,R{-}O\cdot \qquad \textbf{(27.16)}$$

followed by

Propagation:

$$\begin{aligned} CH_2{=}CH_2 + RO\cdot &\longrightarrow R{-}O{-}CH_2{-}CH_2\cdot \\ ROCH_2CH_2\cdot + CH_2{=}CH_2 &\longrightarrow ROCH_2CH_2CH_2CH_2\cdot \qquad \textbf{(27.17)} \\ RO(CH_2)_3CH_2\cdot + CH_2{=}H_2 &\longrightarrow RO(CH_2)_5CH_2\cdot \end{aligned}$$

Termination:

$$RO(CH_2)_xCH_2\cdot + RO\cdot \longrightarrow RO(CH_2)_xCH_2OR \qquad \textbf{(27.18)}$$

or

$$RO(CH_2)_xCH_2\cdot + RO(CH_2)_yCH_2\cdot \longrightarrow RO(CH_2)_xCH_2CH_2(CH_2)_yOR \qquad \textbf{(27.19)}$$

Several polymers formed by chain-reaction polymerization are listed in Table 27.5.

Notice that the termination steps, reactions (27.18) and (27.19), produce a polymer with —OR groups at either end of the chain. The —OR groups have no effect on the properties of the polymer because the polymer has hundreds, possibly thousands, of monomer units, and the —OR groups are only at the ends of each polymer strand. The long chain of monomer units gives the polymer its particular properties, and the group serves only to initiate the reaction and to terminate the polymer chains.

Step-Reaction Polymerization

In **step-reaction polymerization**, also called *condensation polymerization*, the monomers typically have two or more functional groups that react to join the two molecules together. Usually, this involves the elimination of a small molecule, such as H_2O. In chain-reaction polymerization, the reaction of a monomer can occur only at the end of a growing polymer chain, but in step-reaction polymerization, any pair of monomers is free to join into a *dimer*; the dimer can join with a monomer to form a *trimer*; two dimers can join to form a *tetramer*; and so on. Step-reaction polymerization tends to occur slowly and produces polymers of only moderately high molecular masses (less than 10^5 u). The formation of polyethylene glycol terephthalate, Dacron, is illustrated in

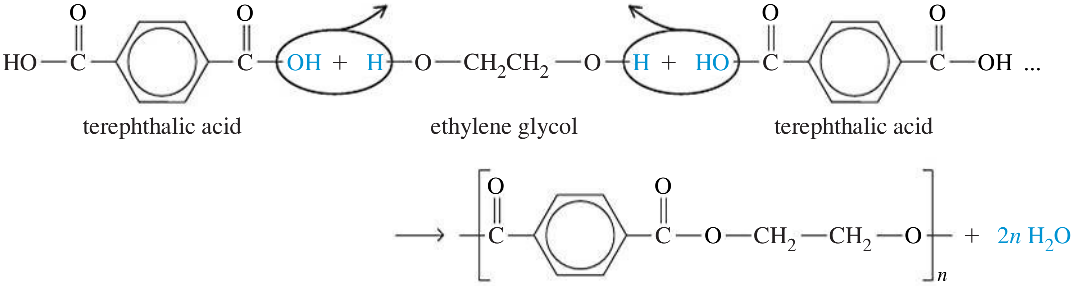
TABLE 27.5 Some Polymers Produced by Chain-Reaction Polymerization

Name	Monomer	Polymer	Uses
Polyethylene	$CH_2{=}CH_2$	$\left(CH_2{-}CH_2\right)_n$	Bags, bottles, tubing, packaging film
Polypropylene	$CH_2{=}CHCH_3$	 $\left(CH_2{-}\underset{CH_3}{\underset{\vert}{CH}}\right)_n$	Laboratory and household ware, artificial turf, surgical casts, toys
Poly(vinyl chloride) PVC	$CH_2{=}CHCl$	 $\left(CH_2{-}\underset{Cl}{\underset{\vert}{CH}}\right)_n$	Bottles, floor tile, food wrap, piping, hoses
Poly(tetrafluoroethylene), Teflon	$CF_2{=}CF_2$	$\left(CF_2{-}CF_2\right)_n$	Bearings, insulation, nonstick surfaces, gaskets, industrial ware
Polystyrene			Packaging, refrigerator doors, cups, ice buckets, and coolers (as foam)

TABLE 27.6 Some Polymers Produced by Step-Reaction Polymerization

Name	Monomer	Polymer	Uses
Poly(ethylene glycol terephthalate) (Dacron)	$HOCH_2CH_2OH$ and 		Textile fabrics, twine and rope, fire hoses, plastic containers
Poly(hexamethyleneadipamide) nylon 66	$H_2N(CH_2)_6NH_2$ and $HOOC(CH_2)_4COOH$	 $\left[-\overset{\overset{O}{\Vert}}{C}-(CH_2)_4-\overset{\overset{O}{\Vert}}{C}-NH-(CH_2)_6-NH-\right]_n$	Hosiery, rope, tire cord, parachutes, artificial blood vessels
Polyurethane	$HO(CH_2)_4OH$ and $OCN(CH_2)_6NCO$	 $\left[-O-(CH_2)_4O-\underset{\underset{O}{\Vert}}{C}-\overset{\overset{H}{\vert}}{N}-(CH_2)_6\overset{\overset{H}{\vert}}{N}-\underset{\underset{O}{\Vert}}{C}-\right]_n$	Spandex fibers, bristles for brushes, cushions and mattresses (as foam)

the following reaction, and several other polymers formed by this method are listed in Table 27.6.

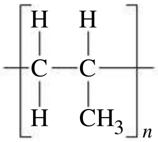


poly(ethylene glycol terephthalate)
(Dacron)

Stereospecific Polymers

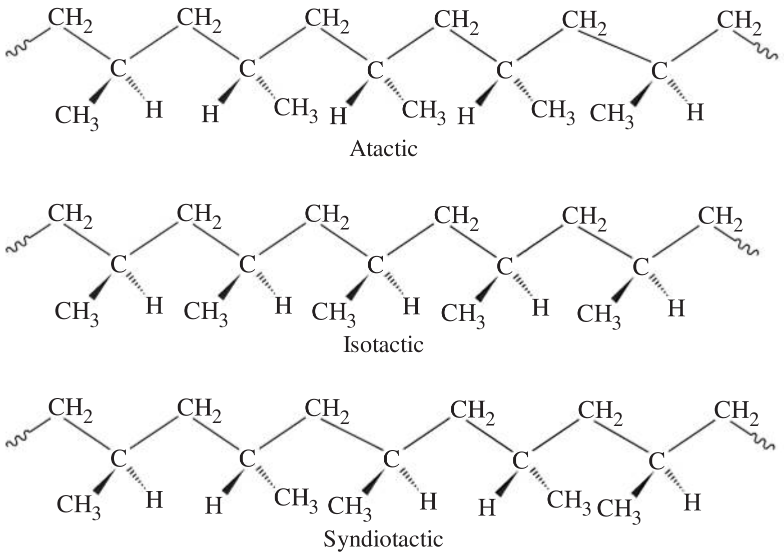
The physical properties of a polymer are determined by a number of factors, such as the average length (average molecular mass) of the polymer chains and the strength of intermolecular forces between chains. Another important factor is whether the polymer chains display any crystallinity—that is, an ordered geometry and spacing of the atoms between polymer chains. In general, amorphous polymers are glass-like or rubbery. A high-strength fiber, on the other hand, must possess some crystallinity. Many polymers have both crystalline and amorphous regions. The relative amount of each type of region affects the physical properties of the polymer.

The usual designation of a polymer, as applied to polypropylene, for example, is not very revealing about the structure of the polymer:



$$\left[-\overset{\overset{H}{\vert}}{\underset{\underset{H}{\vert}}{C}}-\overset{\overset{H}{\vert}}{\underset{\underset{CH_3}{\vert}}{C}}-\right]_n$$

It does not indicate the orientation of the groups along the polymer chain. If propylene is polymerized by the method shown for ethylene on page 1252, the orientation of the groups is random (Fig. 27-23). Apolymer of this type is called *atactic*. Because there is no regularity to the structure, atactic polymers are amorphous. In an *isotactic* polymer, all $-CH_3$ groups have the same orientation, and



▶ FIGURE 27-23
Three representations of a polypropylene chain
In the *atactic* polymer, the —CH_3 groups are randomly distributed on the chain. In the *isotactic* polymer, all —CH_3 groups are shown coming out of the plane of the page. In the *syndiotactic* polymer, —CH_3 groups alternate along the chain—one in front of the plane of the page, the next one behind the plane, and so on.

in a *syndiotactic* polymer, the —CH_3 groups alternate back and forth along the chain. Because of their structural regularity, isotactic and syndiotactic polymers possess crystallinity, which makes them stronger and more resistant to chemical attack than an atactic polymer.

In the 1950s, Karl Ziegler and Giulio Natta developed procedures for controlling the spatial orientation of substituent groups on a polymer chain by using special catalysts, such as $(CH_3CH_2)_3Al + TiCl_4$. This discovery, recognized through the award of a Nobel Prize in 1963, revolutionized polymer chemistry. Through stereospecific polymerization, it is possible to literally tailor-make large molecules.

27-9 Synthesis of Organic Compounds

Originally, all organic compounds were isolated from natural sources. However, as chemists developed an understanding of the chemical behavior of organic compounds, they began to devise methods of synthesizing compounds from simple starting materials. Moreover, some of the compounds synthesized by the newly developed methods had never been observed to occur naturally.

In organic synthesis, chemists attempt to transform simple, readily available compounds into more complex molecules with desirable physical and chemical properties. Some syntheses are designed to make biologically active compounds that are otherwise available only from natural sources and in only small quantities at high cost. Other synthetic approaches are designed to make new compounds, similar to naturally occurring ones but even more powerful in biological activity, such as medications to fight disease.

The approach that a synthetic organic chemist takes is to apply a knowledge of a wide variety of reaction types and reaction mechanisms to devise a synthetic scheme for assembling simple molecules into more complex structures. Figure 27-24 summarizes some of the chemical transformations between functional groups considered in this chapter (and Chapter 26). This summary stresses that each type of reaction has three components: the starting materials, the products, and the required reagents. For any reaction, we can complete a chemical equation if we have information about two of the three components of the reaction and if we know the type of reaction that converts the starting materials to the products. For example, in the following nucleophilic substitution reaction,

$$CH_3Br + ? \longrightarrow CH_3CN + ?$$

◀ FIGURE 27-24 **Some functional group transformations**
A summary of some important functional group transformations, each of which requires a specific reagent as described in the text or on www.masteringchemistry.com. When using this diagram, remember that changes in the R group are not indicated because this depends on the particular group involved. Recall that the symbols 1°, 2°, and 3° stand for primary, secondary, and tertiary, respectively.

we see that CN has been substituted for Br as a functional group. To achieve this transformation, the nucleophile CN^- is required, and we complete the equation:

$$CH_3Br + CN^- \longrightarrow CH_3CN + Br^-$$

A somewhat different, and more common, situation is that represented by

$$? + Br^- \longrightarrow CH_3Br + ?$$

where we need to work backward to decide on the electrophile in a nucleophilic substitution reaction to get the desired product, CH_3Br. The electrophile will need to be connected to the leaving group (for example, another halogen atom) in the same manner and place as the Br atom will be in the product. An appropriate complete equation is

$$CH_3I + Br^- \longrightarrow CH_3Br + I^-$$

Let's apply the approach outlined above to the synthesis of ethyl ethanoate, starting only from inorganic substances and carbon (coke). First, we break the desired compound down into its constituent molecules, namely ethanol and ethanoic acid, which can be combined to give the ester:

$$CH_3COOH + HOCH_2CH_3 \longrightarrow H_2O + CH_3COOCH_2CH_3$$

We therefore need to be able to produce ethanol, which can, in turn, be converted into ethanoic acid:

$$HOCH_2CH_3 \xrightarrow{?} H_3COOH$$

The reagent required to oxidize ethanol is $K_2Cr_2O_7$ in acidic solution. We now need a route to the synthesis of ethanol from carbon. One inorganic reagent that we have at our disposal that contains a —OH group is water. We therefore write the equation

$$? + H_2O \longrightarrow HOCH_2CH_3$$

A consideration of the reactions in Figure 27-24 indicates that one possibility is the addition of water to the double bond in ethene in the presence of sulfuric acid as a catalyst. Thus, we write

$$H_2C{=}CH_2 + H_2O \xrightarrow{H_2SO_4} HOCH_2CH_3$$

To continue, the ethene molecule has to be generated. Ethene is related to ethyne by a hydrogenation reaction:

$$\mathrm{H{-}C{\equiv}C{-}H} + \mathrm{H_2} \xrightarrow[\text{heat and pressure}]{\text{Pt}} \mathrm{H_2C{=}CH_2}$$

Our source of carbon is the element carbon and we need a way of producing a molecule with a carbon-chain length of two. The production of calcium carbide and its subsequent hydrolysis to give ethyne is described on page 1177. We have now completed the description of the desired synthesis. The underlying strategy is to break the desired molecule down into its constituent molecules and work backward, using the chemical transformations available. This approach is known as *retrosynthesis* and is the method of choice in modern synthetic organic chemistry.

Often, in the design of a synthetic pathway, one or more routes are possible. For example, in the synthesis described above, one of the steps required the synthesis of ethanol. We chose to make it by adding H_2O across the double bond of ethene. However, we could have taken another approach. For example, we could have used the following substitution reaction:

$$\mathrm{CH_3CH_2Cl} + \mathrm{OH^-} \longrightarrow \mathrm{CH_3CH_2OH} + \mathrm{Cl^-}$$

To obtain the chloroethane required for this reaction, we could substitute a Cl atom for an H atom in CH_3CH_3 which, in turn, can be produced by the hydrogenation of ethyne.

How do we decide which synthetic pathway is best? Frequently, the chosen pathway is the one that produces the greatest yield of the desired product. However, other factors may need to be considered. What are the yields of the various reactions involved? Are the required reagents readily available and what is their cost? Are the required reagents or intermediate compounds toxic or dangerous, and, if so, are there methods or equipment in place to be able to work with these compounds? Clearly, knowledge of the physical and chemical properties of organic compounds figure prominently in the design of synthetic pathways.

MasteringCHEMISTRY **www.masteringchemistry.com**

Ionic liquids are organic salts with room temperature melting points. They are environmentally friendly, are able to dissolve most organic molecules, have high thermal stabilities and are nonflammable—properties that make these liquids attractive as solvents for organic synthesis. For a discussion of ionic liquids, go to the Focus On feature for Chapter 27, Green Chemistry and Ionic Liquids, on the MasteringChemistry site.

Summary

27-1 Organic Reactions: An Introduction—Organic compounds undergo a variety of reactions. In a **substitution reaction**, an atom, an ion, or a group in one molecule is replaced by another. In an **elimination reaction**, atoms or groups that are bonded to adjacent atoms are removed as a small molecule. In an **addition reaction**, a molecule adds across a double or triple bond in another molecule. In a **rearrangement reaction**, the carbon skeleton (or constitution) of a molecule is rearranged.

27-2 Introduction to Nucleophilic Substitution Reactions—A common reaction involving sp^3-hybridized carbon atoms is a **nucleophilic substitution reaction**, in which a **nucleophile** attacks the **electrophilic** carbon atom of the **substrate** yielding the product and a **leaving group**. The leaving group is the substituent that is displaced from the electrophilic carbon atom during the reaction. The nucleophile contains a pair of electrons that seek the positive carbon atom of the other reactant. **Basicity** is a measure of the tendency of an electron pair donor to react with a proton. The **nucleophilicity** of an electron pair donor depends on a number of factors, including whether the nucleophile is neutral or negatively charged; the electronegativity and size of the nucleophilic atom; whether the nucleophilic atom is sterically hindered; and the solvent. Two mechanisms for nucleophilic substitution reactions are $\mathbf{S_N1}$ and $\mathbf{S_N2}$. The S_N1 mechanism involves two steps: (1) a unimolecular rate-determining step involving the formation of a carbocation, followed by (2) nucleophilic attack of the carbocation (Figs. 27-3 and 27-4). S_N1 reactions occur most rapidly for reactions involving tertiary substrates and weak nucleophiles reacting in a polar **protic solvent**. Methyl and primary substrates do not undergo S_N1 reactions (Table 27.2). The S_N2 mechanism is a concerted bimolecular reaction in which a nucleophile attacks the electrophilic carbon atom from the backside (Figs. 27-1 and 27-2). S_N2 reactions occur most rapidly for reactions involving methyl and primary substrates and good or strong nucleophiles reacting in a polar **aprotic solvent**. If the electrophilic carbon atom is chiral, and if both the nucleophile and leaving group are high in the *R*/*S* priority order, then backside attack (S_N2) leads to an inversion of configuration ($R \leftrightarrow S$) at the chiral carbon.

27-3 Introduction to Elimination Reactions—Under appropriate conditions, haloalkanes undergo elimination reactions to form alkenes. Usually, the major elimination product is the one that is the most highly substituted. An **E1 reaction** is an elimination reaction with a unimolecular rate-determining step, involving carbocation formation, followed by removal of a proton from a β carbon atom (Figs. 27-10 and 27-11). An **E2 reaction** is a concerted, bimolecular reaction (Fig. 27-12). Elimination reactions compete with nucleophilic substitution reactions. S_N1 and E1 reactions always occur together. The use of a strong base favors elimination by E2 and the use of a weak base favors substitution by either S_N1 or S_N2 (Fig. 27-13).

27-4 Reactions of Alcohols—Alcohols undergo a variety of reactions (Table 27.3). Like haloalkanes, alcohols can undergo substitution or elimination reactions. These reactions require the use of an acid catalyst (Figs. 27-14 and 27-15). When an alcohol acts as the substrate in a substitution reaction, the —OH group is replaced by another group. When an alcohol acts as the substrate in an elimination reaction, an alkene and a water molecule are produced (reaction 27.6). The elimination of water from an alcohol is also called a **dehydration reaction**.

27-5 Introduction to Addition Reactions: Reactions of Alkenes—The characteristic reaction of alkenes is the addition of two substituents to each of the carbon atoms in the double bond (reaction 27.7). A variety of addition reactions are possible: hydrogenation; addition of hydrogen halides (reaction 27.8); hydration (reaction 27.9), producing a **vicinal dihalide** or a **geminal dihalide**; and halogenation (reaction 27.10). In these reactions, a transfer of electron density occurs from the π bond of the alkene to an electrophilic atom. In all these reactions—except halogenation—the electrophilic atom tends to add to the least-substituted carbon atom of the double bond, yielding a carbocation that has the positive charge localized on the more highly substituted carbon atom. In a halogenation reaction, a **bridged halonium ion** is formed in which a halogen atom is bonded to both carbon atoms (Fig. 27-20). The halonium ion is then attacked from the backside by a halide ion.

27-6 Electrophilic Aromatic Substitution—Benzene reacts with electrophiles in substitution reactions in which any of the six H atoms is replaced by another atom or group. In a nitration reaction, $-H$ is replaced by $-NO_2$; in a halogenation reaction, $-H$ is replaced by a halogen atom ($-X$). Nitration and halogenation of benzene are examples of an **electrophilic substitution reaction** (reaction 27.11). An electrophilic substitution reaction involves two steps: (1) an electrophilic attack of a carbon atom in the benzene ring, forming a carbocation called an **arenium ion**; and (2) the loss of a proton to a base (Fig. 27-21). Derivatives of benzene can also undergo substitution reactions. A substituent that is bonded to the carbon atom in a benzene ring can be *ortho*, *para* directing, or *meta* directing.

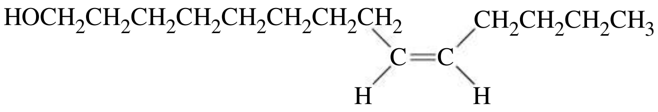
27-7 Reactions of Alkanes—Alkanes and other hydrocarbons react with oxygen during combustion to form carbon dioxide and water (reaction 27.14). Alkanes are relatively unreactive except with the halogens, which can substitute for hydrogen atoms in a substitution reaction (reaction 27.15). The halogenation of alkanes occurs by a chain reaction that involves initiation, propagation, and termination steps. Among the halogens, bromine shows the greatest selectivity for which hydrogen atom in an alkane is replaced: $3^\circ > 2^\circ > 1^\circ >$ methyl.

27-8 Polymers and Polymerization Reactions—Polymers are a very important class of substances in modern life. One method of polymerization, the joining of monomers to form polymers, is called **step-reaction polymerization**, or condensation polymerization. It produces polymers of moderate molecular mass. Another type of polymerization mechanism is **chain-reaction polymerization**, a three-step process involving initiation (reaction 27.16), propagation (reaction 27.17), and termination (reaction 27.18), producing polymers of high molecular mass.

27-9 Synthesis of Organic Compounds—The synthesis of larger and more complex organic compounds from simpler precursors can be achieved through a sequence of reactions of different types and varied mechanisms. Figure 27-24 summarizes a number of functional group transformations that can be used in designing synthetic strategies. One powerful strategy is to work backward from the desired product to the starting materials, a method known as retrosynthesis.

Integrative Example

The female of a species of worm produces the sex attractant *spodoptol*, which has the following structure.



Spodoptol

Spodoptol is a pheromone that attracts the male worms of the species. Synthetic spodoptol in traps can be used to control the population of worms. Devise a synthesis of spodoptol starting from the alcohol shown below.

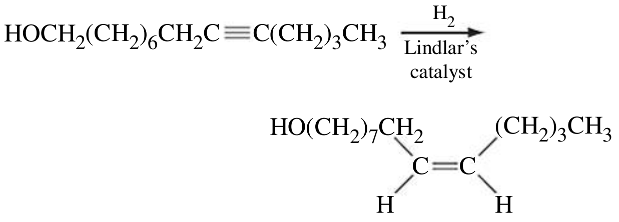
$$HOCH_2CH_2CH_2CH_2CH_2CH_2CH_2CH_2C\equiv CH$$

Analyze

In designing the synthesis, we break down the spodoptol molecule into the starting material and the necessary alkyl group that has to be attached to a double bond, namely a *n*-butyl group. In order to produce the alkene skeleton structure, we will have to convert the triple bond in the starting material to a double bond with *cis* stereochemistry.

Solve

Working backward, this *cis* isomer is obtained by using Lindlar's catalyst (recall page 1240).



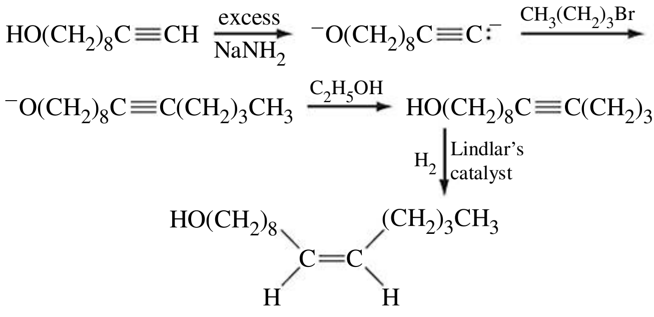
Now we need to make the alkyne needed in the above hydrogenation. The starting material provided lacks the butyl group at the triple bond. To attach the alkyl group, we can perform a nucleophilic substitution at 1-bromobutane with the acetylide ion generated from the starting material, by using sodium amide:

$$^{-}O(CH_2)_8C\equiv C:^{-} + CH_3(CH_2)_3Br \longrightarrow {}^{-}O(CH_2)_8C\equiv C(CH_2)_3CH_3 + Br^{-}$$

Because the alcohol proton of the acetylide is also acidic, we need to add an *excess* of sodium amide to give the combined alkoxide and acetylide. (Ammonia is also produced in the reaction.)

$$HO(CH_2)_8C\equiv CH \xrightarrow[NaNH_2]{\text{excess}} {}^{-}O(CH_2)_8C\equiv C:^{-}$$

We can now combine these steps into a complete synthesis where we have converted the alkoxide to the alcohol in the next-to-last step by adding ethanol. The ethanol gives up a proton to the alkoxide we have synthesized (the ethoxide ion is the weaker base).



Assess

By using the backward synthetic approach—retrosynthesis—we have established a possible synthetic pathway for the synthesis of spodoptol from the starting material. This is a common approach in the development of a synthetic route to a target compound. A proposed synthesis should always be carefully examined to assess whether side reactions are possible because they can decrease the yield of the desired product. In the present case, a side reaction is possible in the second step above. The $—O(CH_2)_8CC—$ ion could also react with $CH_3(CH_2)_3Br$ to give an ether.

PRACTICE EXAMPLE A: How could 1,3-cyclohexadiene be synthesized from cyclohexane?

PRACTICE EXAMPLE B: How could the compound at right be prepared from benzene by using electrophilic aromatic substitution reactions discussed in this chapter?

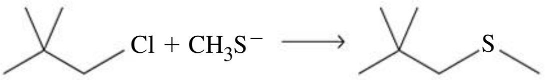
Exercises

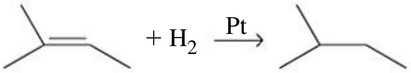
Types of Organic Reactions

1. Describe what is meant by each of the following reaction types, and illustrate with an example: **(a)** nucleophilic substitution reaction; **(b)** electrophilic substitution reaction; **(c)** addition reaction; **(d)** elimination reaction; **(e)** rearrangement reaction.
2. Describe what is meant by each of the following reaction types, and illustrate with an example from the text: **(a)** dehydration; **(b)** hydrolysis; **(c)** solvolysis; **(d)** hydration of an alkene.
3. Identify the following types of reactions.

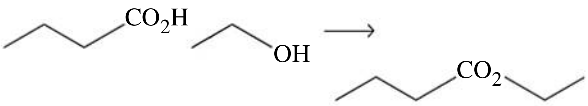
(a)



(b)

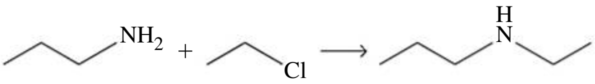


(c)

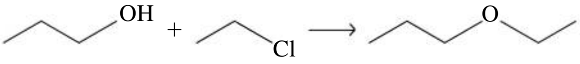


4. Identify the following types of reactions.

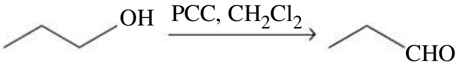
(a)



(b)



(c)



Note: PCC is pyridinium chlorochromate (see page 1185).

5. Write a balanced chemical equation for the reaction that is described and then classify the reaction as a substitution, an elimination, an addition, or a rearrangement reaction:
   (a) Ethene and Br_2 react in carbon tetrachloride to give 1,2-dibromoethane.
   (b) Iodoethane reacts with KOH(aq) yielding ethene, water, and potassium bromide.
   (c) Chloromethane reacts with NaOH(aq) to give methanol and sodium chloride.
6. Write a balanced chemical equation for the reaction that is described and then classify the reaction as a substitution, an elimination, an addition, or a rearrangement reaction.
   (a) 3,3-dimethyl-1-butene reacts in acid solution to yield 2,3-dimethyl-2-butene.
   (b) 1-iodo-2,2-dimethylpropane reacts with water, 2,2-dimethyl-1-propanol, and HI(aq).
   (c) 2-chloro-2-methylpropane reacts with NaOH(aq) to give 2-methyl-1-propene, sodium chloride, and water.

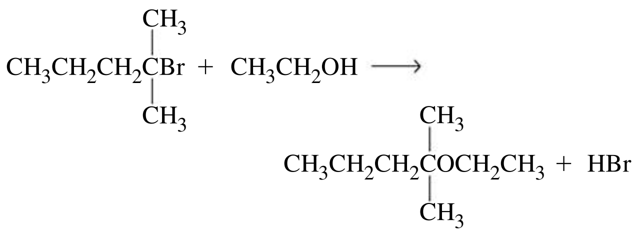
Substitution and Elimination Reactions

7. Write equations for the substitution reaction of *n*-bromobutane, a typical primary haloalkane, with the following reagents: **(a)** NaOH; **(b)** NH_3; **(c)** NaCN; **(d)** CH_3CH_2ONa.
8. Write equations for the substitution reaction of *n*-bromopentane, a typical primary haloalkane with the following reagents: **(a)** NaN_3; **(b)** $N(CH_3)_3$; **(c)** $CH_3CH_2C{\equiv}CNa$; **(d)** CH_3CH_2SNa.
9. Answer the following questions for this S_N2 reaction:

$$CH_3CH_2CH_2CH_2Br + NaOH \longrightarrow CH_3CH_2CH_2CH_2OH + NaBr$$

   (a) What is the rate expression for the reaction?
   (b) Draw the reaction profile for the reaction. Label all parts. Assume that the products are lower in energy than the reactants.
   (c) What is the effect on the rate of the reaction of doubling the concentration of *n*-butyl bromide?
   (d) What is the effect on the rate of the reaction of halving the concentration of sodium hydroxide?

10. Answer the following questions for this S_N1 reaction:



$$CH_3CH_2CH_2\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{C}}Br + CH_3CH_2OH \longrightarrow CH_3CH_2CH_2\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{C}}OCH_2CH_3 + HBr$$

(a) What is the rate expression for the reaction?
(b) Draw the reaction profile for the reaction. Label all parts. Assume that the products are lower in energy than the reactants.
(c) What is the effect on the rate of the reaction of doubling the concentration of 1-bromo-1-methylpentane?
(d) The solvent for the reaction is ethanol. What is the effect on the rate of the reaction of adding more ethanol?

11. Answer the following questions for this E2 reaction:

$$CH_3CH_2CH_2Br + NaOH \longrightarrow CH_3CH{=}CH_2 + NaBr + H_2O$$

(a) What is the rate expression for the reaction?
(b) Draw the reaction profile for the reaction. Label all parts. Assume that the products are lower in energy than the reactants.
(c) What is the effect on the rate of the reaction of doubling the concentration of $CH_3CH_2CH_2Br$?
(d) What is the effect on the rate of the reaction of halving the concentration of NaOH?

12. Answer the following questions for this E1 reaction:

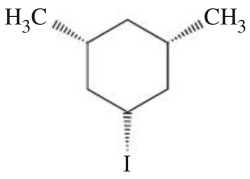
$$CH_3CH_2C(CH_3)_2Br + CH_3OH \longrightarrow CH_3CH{=}C(CH_3)_2 + Br^- + CH_3OH_2^+$$

(a) What is the rate expression for the reaction?
(b) Draw the reaction profile for the reaction. Label all parts. Assume that the products are lower in energy than the reactants.
(c) What is the effect on the rate of the reaction of doubling the concentration of $CH_3CH_2C(CH_3)_2Br$?
(d) What is the effect on the rate of the reaction of doubling the concentration of CH_3OH?

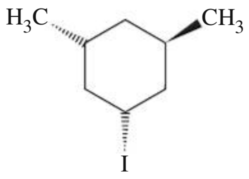
13. Identify the nucleophile, electrophile, and leaving group in each of the following substitution reactions. Predict whether equilibrium favors the reactants or products:
(a) $CH_3CH_2ONa + CH_3CH_2CH_2I \rightleftharpoons CH_3CH_2CH_2OCH_2CH_3 + NaI$
(b) $CH_3CH_2NH_3^+ + KI \rightleftharpoons NH_3 + CH_3CH_2I + K^+$

14. Identify the nucleophile, electrophile, and leaving group in each of the following substitution reactions. Predict whether equilibrium favors the reactants or products:
(a) $CH_3OH + I^- \rightleftharpoons CH_3OH + NaOH$
(b) $(CH_3)_2CHCl + KCN \rightleftharpoons (CH_3)_2CHCN + KCl$

15. Molecule (a) below reacts faster in the S_N2 reaction than does molecule (b). Explain this observation. [*Hint*: Draw chair structures for the most stable conformations of the two molecules.]



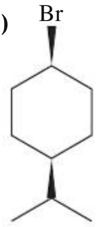
(a)



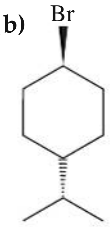
(b)

16. Molecule (a) below reacts faster in the S_N1 reaction than does molecule (b). Explain this observation. [*Hint*: Draw chair structures for the two molecules.]

(a)



(b)



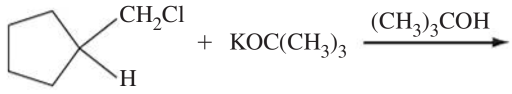
17. A sample of (S)-$CH_3CH_2CH(CH_3)Cl$ is hydrolyzed by water, and the resulting solution is optically inactive. **(a)** Write the formula of the product. **(b)** By which nucleophilic substitution reaction mechanism does this reaction occur?

18. A sample of (R)-$CH_3CH_2CH(CH_3)Cl$ reacts with CH_3O^- in dimethyl sulfoxide, $(CH_3)_2SO$, a convenient solvent for organic reactions. The resulting solution is optically active. **(a)** Write the formula of the product. **(b)** By which mechanism does this nucleophilic substitution reaction occur?

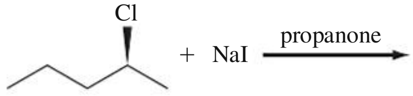
19. A sample of (S)-$CH_3CH(Cl)CH_2CH_3$ is dissolved in ethanol, and the resulting solution is optically inactive. **(a)** Write the formula of the product. **(b)** By which mechanism does this nucleophilic substitution reaction occur?

20. A sample of (R)-$CH_3CH(Cl)CH_2CH_3$ reacts with CH_3S^- in dimethyl sulfoxide, and the resulting solution is optically active. **(a)** Write the formula of the product. **(b)** By which mechanism does this nucleophilic substitution reaction occur?

21. Give the major products obtained in each of the following reactions and indicate which mechanisms are involved:
(a)

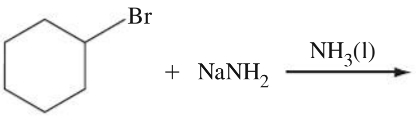


(b)



(c) (S)-$(CH_3)_3CCHBrCH_3 + CH_3CH_2OH \longrightarrow$

22. Give the major products obtained in each of the following reactions and indicate which mechanisms are involved:
(a)



(b) $(CH_3)_2CHCH_2CH_2CH_2Br + NaOCH_2CH_3 \xrightarrow{CH_3CH_2OH}$
(c) (R)-2-iodobutane + NaHS $\xrightarrow{DMSO}$

Alcohols and Alkenes

23. Predict the major organic product obtained in each of the following reactions. Assume that [O] represents $Na_2Cr_2O_7$ in H_2SO_4:
(a) $(CH_3)_2CHCH_2OH + HBr \longrightarrow$
(b) $(CH_3)_3COH + K \longrightarrow$
(c) $(CH_3)_2CHOH \xrightarrow{[O]}$
(d) $CH_3CH_2CH_2OH + CH_3CH_2I \longrightarrow$

24. Predict the products of the following reactions. Assume that [O] represents $Na_2Cr_2O_7$ in H_2SO_4:

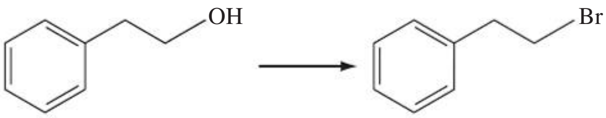
(a) $(CH_3)_2CHCH_2OH \xrightarrow{[O]}$

(b) $CH_3CH_2OH + (CH_3)_2CHCOOH \xrightarrow[\Delta]{H^+}$

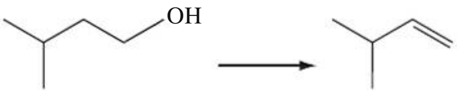
(c) 3-methyl-2-butanol + NaCl $\xrightarrow{H_2SO_4}$

(d) $CH_3CH_2CH_2OH \xrightarrow[\Delta]{H_2SO_4}$

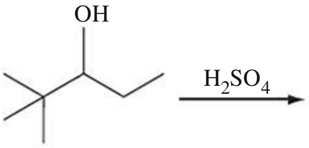
25. Explain how you could carry out the following conversion. Write a mechanism for the reaction:



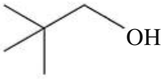
26. Explain how you could carry out the following conversion. Write a mechanism for the reaction:



27. As discussed in Are You Wondering 27-2, carbocation rearrangements occur in some substitution and elimination reactions. What elimination product would you expect in the following reaction *if no rearrangement of the carbocation occurs*? Experiment reveals that the main product is 2,3-dimethyl-2-pentene. Suggest a mechanism that shows how 2,3-dimethyl-2-pentene is formed. [*Hint:* Consider the formation and rearrangement of a carbocation.]



28. The molecule below is 2,2-dimethyl-1-propanol, a primary alcohol. Because no H atoms are bonded to the β carbon atom in this molecule, dehydration seems unlikely. However, when 2,2-dimethyl-1-propanol is heated with an acid catalyst, 2-methyl-2-butene is obtained. Suggest a mechanism that shows how 2-methyl-2-butene is formed. [*Hint:* Consider the formation and rearrangement of a carbocation. See Are You Wondering 27-2.]



29. Draw the structures of the products of each of the following reactions:

(a) propene + hydrogen (Pt, heat)

(b) 2-butanol + heat (in the presence of sulfuric acid)

30. Predict the product(s) of the reaction of:

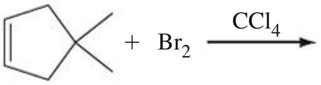
(a) HCl with 2-chloro-1-propene

(b) HCN with $CH_3CH{=}CH_2$

(c) HCl with $CH_3CH{=}C(CH_3)_2$

31. Give the structures of the main organic product(s) in each of the following reactions.

(a)



(b) (Z)-2-butene + HI $\longrightarrow$

(c) 2-methyl-1-butene + $H_2O \xrightarrow{H_2SO_4}$

32. Give the structure of the main organic product(s) in each of the following reactions:

(a) (E)-2-butene + HBr $\longrightarrow$

(b) 2-methyl-2-pentene + $H_2O \xrightarrow{H_2SO_4}$

(c)

33. Give the major product that forms when (*Z*)-3-methyl-2-pentene reacts with each of the following reagents: **(a)** HI; **(b)** H_2 in the presence of a platinum catalyst; **(c)** H_2O in H_2SO_4; **(d)** Br_2 in CCl_4.

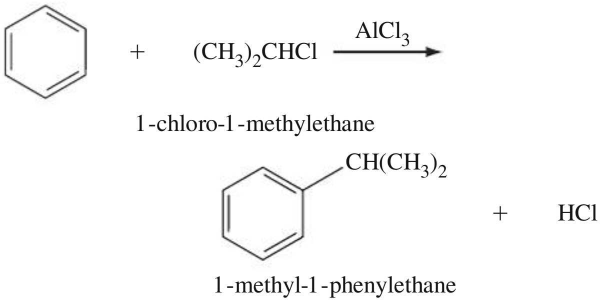
34. Give the major product that forms when 1-ethylcyclohexene reacts with each of the following reagents: **(a)** HI; **(b)** H_2 in the presence of a platinum catalyst; **(c)** H_2O in H_2SO_4; **(d)** Br_2 in CCl_4.

Electrophilic Aromatic Substitution

35. Sketch the reaction profile for the mechanism depicted in Figure 27-21, by assuming the overall reaction is exothermic. Also, experimental evidence suggests that the activation energy for the first step is greater than the activation energy for the second step. Draw structures for the intermediate and transition states.

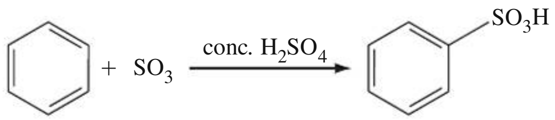
36. The chlorination of benzene can be carried out by allowing benzene to react with Cl_2 in the presence of $AlCl_3$. As discussed on page 1245, Cl_2 and $AlCl_3$ react to form $Cl^+AlCl_4^-$. Sketch the reaction profile for the reaction of benzene and $Cl^+AlCl_4^-$. Use the same assumptions as in Exercise 35.

37. Alkylation of benzene can be accomplished by treating benzene with haloalkane (RX) in the presence of $AlCl_3$. The reaction is known as a Friedel–Crafts alkylation reaction. (The reaction is named after Charles Friedel, a French chemist, and James M. Crafts, an American chemist, who discovered this method of making alkylbenzenes in 1877.) An example of a Friedel–Crafts alkylation reaction is shown below:



The mechanism for this reaction involves the following steps. First, $(CH_3)_2CHCl$ and $AlCl_3$ react in a Lewis acid–base reaction to form an adduct, $(CH_3)_2CH—Cl—AlCl_3$, in which a chlorine atom is bonded to both carbon and aluminum. The adduct then dissociates to $(CH_3)_2CH^+$, a carbocation, and $AlCl_4^-$. The carbocation acts as an electrophile in a reaction with benzene, forming an arenium ion. Finally, a proton is removed from the arenium ion by $AlCl_4^-$, yielding an alkylbenzene, HCl, and $AlCl_3$. Write chemical equations for the elementary processes involved in forming 1-methyl-1-phenylethane and HCl from $(CH_3)_2CHCl$ and benzene. Use curved arrows to show the movement of electrons.

38. Treating benzene with fuming sulfuric acid yields benzenesulfonic acid, which is formed by the following reaction:



Benzenesulfonic acid

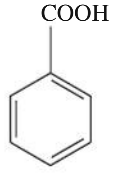
The SO_3 that participates in the reaction above is formed by the reaction of sulfuric acid molecules:

$$2\,H_2SO_4 \longrightarrow SO_3 + HSO_4^- + H_3O^+$$

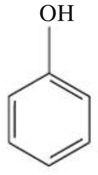
The reaction of benzene and SO_3 to give benzenesulfonic acid involves the following elementary processes. SO_3 acts as an electrophile in a reaction with benzene, forming an arenium ion. A proton is then transferred from the arenium ion to HSO_4^-, forming the benzenesulfonate ion, $C_6H_5SO_3^-$, and H_2SO_4. Finally, $C_6H_5SO_3^-$ is protonated by H_3O^+ to give benzenesulfonic acid and a water molecule. Write balanced chemical equations for these elementary processes, using curved arrows to show the movement of electrons.

39. Predict the main product(s) of **(a)** the mononitration of chlorobenzene; **(b)** the monosulfonation of nitrobenzene; **(c)** the monochlorination of 1-methyl-2-nitrobenzene

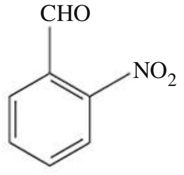
40. Predict the main product(s) of **(a)** the mononitration of benzoic acid; **(b)** the monosulfonation of phenol; **(c)** the monobromination of 2-nitrobenzaldehyde.



Benzoic acid



Phenol



2-nitrobenzaldehyde

Reactions of Alkanes

41. What is major product expected from the monobromination of 2,2,3-trimethylpentane?

42. What is the major product expected from the monobromination of methylcyclohexane?

43. **(a)** Write the initiation, propagation, and termination steps involved in the monofluorination of 2,3-dimethylbutane to give 1-fluoro-2,3-dimethylbutane. **(b)** Explain why in the monofluorination of 2,3-dimethylbutane the major product is 1-fluoro-2,3-dimethylbutane, not 2-fluoro-2,3-dimethylbutane.

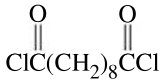
44. Write the initiation, propagation, and termination steps involved in the monobromination of 2,3-dimethylbutane to give 2-bromo-2,3-dimethylbutane.

Polymerization Reactions

45. In referring to the molecular mass of a polymer, we can speak only of the average molecular mass. Explain why the molecular mass of a polymer is not a unique quantity, as it is for a substance like benzene.

46. Explain why Dacron is called a polyester. What is the percent oxygen, by mass, in Dacron?

47. Nylon 66 is produced by the reaction of 1,6-hexanediamine with adipic acid. A different nylon polymer is obtained if sebacyl chloride is substituted for the adipic acid. What is the basic repeating unit of this nylon structure?



$$\mathrm{Cl}\overset{\overset{\displaystyle O}{\|}}{C}(CH_2)_8\overset{\overset{\displaystyle O}{\|}}{C}\mathrm{Cl}$$

48. Would you expect a polymer to be formed by the reaction of terephthalic acid with ethyl alcohol in place of ethylene glycol? With glycerol in place of ethylene glycol? Explain.

Synthesis of Organic Compounds

49. Starting with acetylene as the only source of carbon, together with any inorganic reagents required, devise a method to synthesize acetaldehyde.

50. Starting with acetylene as the only source of carbon, together with any inorganic reagents required, devise a method to synthesize 1,1,2,2-tetrabromoethane.

51. How would you synthesize (*E*)- and (*Z*)-3-heptene from acetylene and any other chemicals?

52. How would you synthesize (*R*)-2-butanamine from (*S*)-2-butanol?

53. The azide anion is a nucleophile and when attached to a carbon atom, undergoes reduction to the amino group and free nitrogen. Suggest a method of preparation of the primary amine propanamine.

54. The cyanide anion is a nucleophile and when attached to a carbon atom, is reduced to a primary amine. Suggest a method of preparing propanamine from chloroethane.

Integrative and Advanced Exercises

55. Draw a structure to represent the principal product of each of the following reactions:
(a) 1-pentanol + dichromate ion (acid solution)
(b) butyric acid + ethanol (acid solution)
(c) 2-methyl-1-butene + HBr

56. Predict the products of the monobromination of **(a)** *m*-dinitrobenzene; **(b)** aniline; **(c)** *p*-bromoanisole.

57. Write the formulas of the products formed from the reaction of propene with each of the following substances: **(a)** H_2; **(b)** Cl_2; **(c)** HCl; **(d)** H_2O (in acid).

58. Write the formulas of the products formed from the reaction of 2-butene with each of the following substances: **(a)** H_2; **(b)** Cl_2; **(c)** HCl; **(d)** H_2O (in acid).

59. Which of the following species gives the reaction indicated? Write the structures of the reaction products.

(1) $CH_3CH_2\overset{O}{\overset{\|}{C}}{-}OCH_3$

(2) $CH_3CH_2\overset{O}{\overset{\|}{C}}{-}OH$

(3) $CH_3\overset{O}{\overset{\|}{C}}{-}O^-$

(a) reacts with dilute HCl
(b) hydrolyzes
(c) neutralizes dilute NaOH

60. Which of the following species gives the reaction indicated? Write the structures of the reaction products.

(1) $CH_3CH_2\overset{O}{\overset{\|}{C}}{-}NH_2$

(2) $CH_3CH_2NH_2$ **(3)** $CH_3CH_2CH_2NH_3{}^+Cl^-$

(a) neutralizes dilute HCl
(b) hydrolyzes
(c) neutralizes dilute NaOH

61. Write the formulas of the products expected to form in the following situations. If no reaction occurs, write N.R.
(a) $CH_3CH_2NH_2(aq) + HCl(aq) \longrightarrow$
(b) $(CH_3)_3N(aq) + HBr(aq) \longrightarrow$
(c) $CH_3CH_2NH_3{}^+(aq) + H_3O^+(aq) \longrightarrow$
(d) $CH_3CH_2NH_3{}^+(aq) + OH^-(aq) \longrightarrow$

62. Write the formulas of the products expected to form in the following situations. If no reaction occurs, write N.R.

(b) $(CH_3)_4N^+(aq) + HCl(aq) \longrightarrow$

(a)  NH(aq) + HCl(aq) $\longrightarrow$

(c) $CH_3CH_2NH_2(aq) + OH^-(aq) \longrightarrow$
(d) $(CH_3)_3NH^+ + OH^- \longrightarrow$

63. To prepare methyl ethyl ketone, which of these compounds would you oxidize: 2-propanol, 1-butanol, 2-butanol, or *tert*-butyl alcohol? Explain.

64. Indicate the principal product(s) you would expect in **(a)** treating $CH_3CH_2CH{=}CH_2$ with *dilute* $H_2SO_4(aq)$; **(b)** exposing a mixture of chlorine and propane gases to ultraviolet light; **(c)** heating a mixture of isopropyl alcohol and benzoic acid; **(d)** oxidizing *sec*-butyl alcohol with $Cr_2O_7{}^{2-}$ in acidic solution.

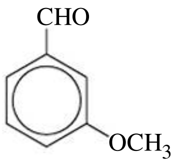
65. Match the following compounds with the chemical properties given below. Write the structure of the products of the reactions described in (a) to (e).

(1) 
(2) 
(3) 
(a) is easily oxidized
(b) neutralizes NaOH(aq)
(c) forms an ester with ethanol
(d) can be oxidized to a carboxylic acid
(e) can be dehydrated to an alcohol

66. Match the following compounds with the chemical properties given below. Write the structure of the products of the reactions described in (a) to (e).

(1) 
(2) 
(3) 
(a) neutralizes HCl(aq)
(b) neutralizes NaOH(aq)
(c) forms an amide with ethanoic acid
(d) reacts with ammonia
(e) reacts with $CN^-(aq)$

67. Write the structures of the isomers you would expect to obtain in the mononitration of *m*-methoxybenzaldehyde:

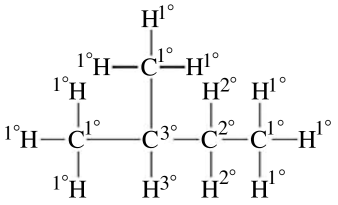


68. In the chlorination of CH_4, some CH_3CH_2Cl is obtained as a product. Explain why this should be so.

69. The three isomeric tribromobenzenes, I, II, and III, when nitrated, form three, two, and one mononitrotribromobenzenes, respectively. Assign correct structures to I, II, and III.

70. Write the name and structure of the benzene derivatives described below.
(a) Formula: C_8H_{10}; forms three monochlorination products when treated with Cl_2 and $FeCl_3$
(b) Formula: C_9H_{12}; forms one monochlorination product when treated with Cl_2 and $FeCl_3$
(c) Formula: C_9H_{12}; forms four monochlorination products when treated with Cl_2 and $FeCl_3$

71. For the monochlorination of hydrocarbons, the following ratio of reactivities has been found: $3^\circ > 2^\circ > 1^\circ$, 4.3 : 3 : 1. How many different monochloro derivatives of 2-methylbutane are possible, and what percentage of each would you expect to find?



72. The cyanide anion is a nucleophile and when attached to a carbon atom, undergoes hydrolysis under basic conditions to the carboxylate anion. Suggest a method of preparing sodium butanoate from chloropropane. How can sodium butanoate be converted into butanoic acid?

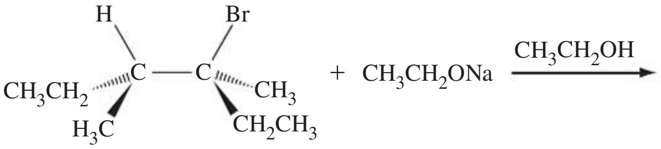
73. The iodide ion cannot displace the —OH group in ethanol, but excess HI will react to produce ethyl iodide. Explain.

74. Starting with the compounds chloromethane, chloroethane, sodium azide, sodium cyanide, and a reducing agent, suggest how the following compounds could be synthesized.
(a) *N*-methylpropanamide
(b) ethylethanoate
(c) methylethylamine
(d) tetramethylammonium chloride

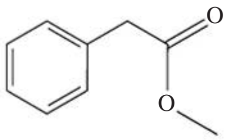
75. Predict and name the product(s) obtained from the following reaction. Write out the mechanism for the reaction and use curved arrows to show the movement of electrons.

$$(CH_3)_2CHCH{=}CH_2 \xrightarrow{H_2SO_4,\ H_2O}$$

76. Predict and name the product(s) obtained from the following reaction. Write out the mechanism for the reaction and use curved arrows to show the movement of electrons.



77. Starting with benzene and methane, and suitable inorganic reagents, suggest how the following compound might be synthesized. [*Hint:* See Exercise 37 for a description of how an alkyl group can be added to the benzene ring.]

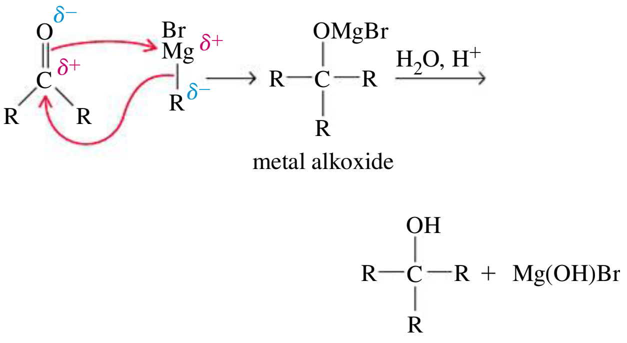


Feature Problem

78. The reduction of aldehydes and ketones with a suitable hydride-containing reducing agent is a good way of synthesizing alcohols. This approach would be even more effective if, instead of a hydride, we could use a source of nucleophilic carbon. Attack by a carbon atom on a carbonyl group would give an alcohol and simultaneously form a carbon-to-carbon bond. How can we make a C atom in an alkane nucleophilic? This was achieved by Victor Grignard, who created the organometallic reagent R—MgBr, with the following reaction in diethyl ether:

$$R{-}Br + Mg \longrightarrow R{-}MgBr$$

The Grignard reagent is rarely isolated. It is formed in solution and used immediately in the desired reaction. The alkylmetal bond is highly polar, with the partial negative charge on the C atom, which makes the C atom highly nucleophilic. The Grignard reagent (R—MgBr) can attack a carbonyl group in an aldehyde or ketone as follows:



Addition of dilute aqueous acid solution to the metal alkoxide furnishes the alcohol. The important synthetic consequence of this procedure is that we have prepared a product with more carbon atoms than present in the starting material. A simple starting material can be transformed into a more complex molecule.

(a) What is the product of the reaction between methanal and the Grignard reagent formed from 1-bromobutane after the addition of dilute acid?
(b) By using a Grignard reagent, devise a synthesis for 2-hexanol.
(c) By using a Grignard reagent, devise a synthesis for 2-methyl-2-hexanol.
(d) Grignard reagents can also be formed with aryl halides, such as chlorobenzene. What would be the product of the reaction between the Grignard reagent of chlorobenzene and propanone? Can you think of an alternative synthesis of this product, again using a Grignard reagent?
(e) The basicity of the C atom bound to the magnesium in the Grignard reagent can be used to make Grignard reagents of terminal alkynes. Write the equation of the reaction between ethylmagnesium bromide and 1-hexyne. [*Hint:* Ethane is evolved.]
(f) By using a Grignard reagent, suggest a synthesis for 2-heptyn-1-ol.

Self-Assessment Exercises

79. Explain the important distinctions between each pair of terms: **(a)** nucleophilic substitution and electrophilic aromatic substitution; **(b)** addition and elimination; **(c)** S_N1 and S_N2; **(d)** E1 and E2

80. Explain the important distinctions between each pair of terms: **(a)** base and nucleophile; **(b)** α carbon and β carbon; **(c)** polar protic solvent and polar aprotic solvent; **(d)** carbocation and radical.

81. **(a)** Which of the nucleophiles CN^- or Cl^- reacts faster with CH_3CH_2I in an S_N2 reaction?
(b) Which of the substrates, $CH_3CH_2CH(CH_3)CH_2I$ or CH_3I, reacts faster with OH^- in an S_N2 reaction?

82. Which of the following is the strongest nucleophile for an S_N2 reaction? **(a)** H_2O; **(b)** CH_3CH_2OH; **(c)** $CH_3CH_2O^-$; **(d)** $CH_3CO_2{}^-$; **(e)** CH_3S^-.

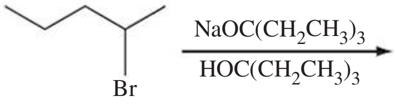
83. Which of the following reactions would give a better yield of $CH_3OCH(CH_3)_2$? Explain.

$$CH_3ONa + (CH_3)_2CHI \longrightarrow CH_3OCH(CH_3)_2 + NaI$$

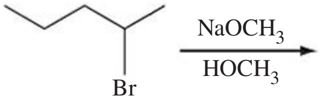
$$(CH_3)_2CHONa + CH_3I \longrightarrow CH_3OCH(CH_3)_2 + NaI$$

84. What is the major elimination product obtained in the following reactions?

(a)

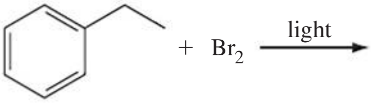


(b)

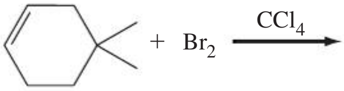


85. What is the major organic product obtained in the following reactions?

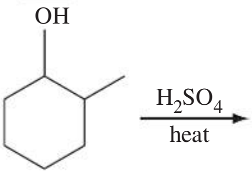
(a)



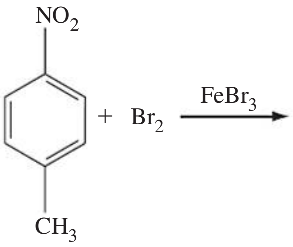
(b)



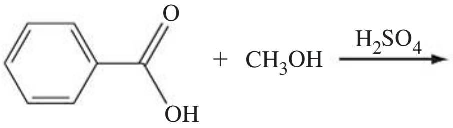
(c)



(d)



(e)



86. When $(CH_3CH_2)_3CBr$ is added to CH_3OH at room temperature, the major product is $CH_3O(CH_2CH_3)_3$ and a minor product is $CH_3CH{=}C(CH_2CH_3)_2$. Write out the mechanisms for the reactions leading to these products and use curved arrows to show the movement of electrons.

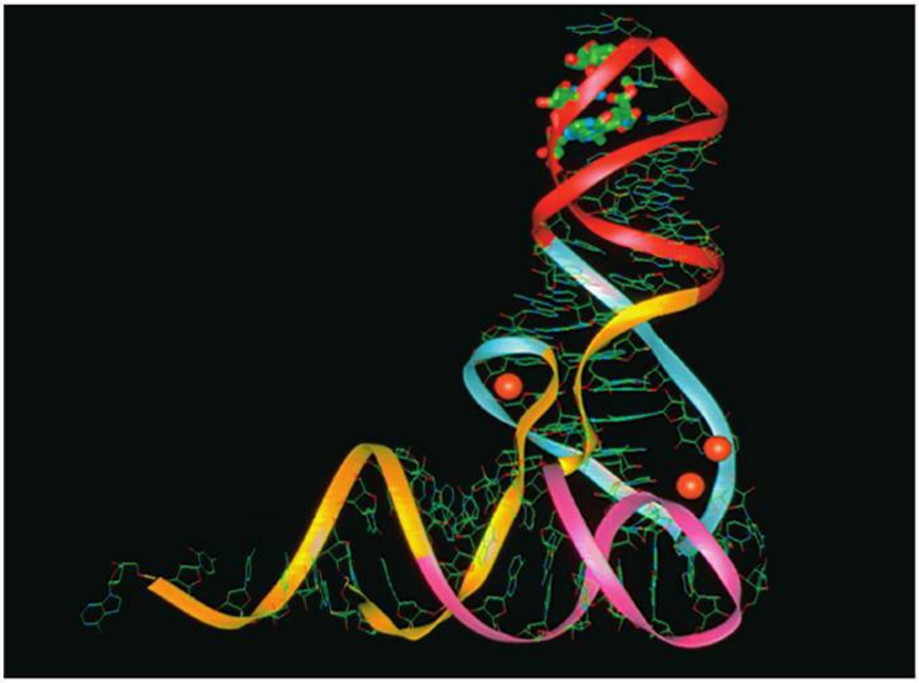
28-6 Nucleic Acids



Transfer ribonucleic acid, tRNA, shown as a ribbon model. A wire frame model of tRNA is superimposed on the ribbon model. The red spheres represent magnesium ions, and the red and green spheres at the top highlight the anticodon triplet. As we learn in this chapter, nucleic acids are important components in the chemistry of life.

The planet Earth teems with life—from the tiny bacterium to the enormous whale. In spite of extraordinary differences in outward appearance, all living organisms share similar needs and chemical structures. Raw materials (food) are required for building cells and providing the energy of metabolism. The cells of almost all forms of living things on Earth use the same types of complicated structures to perform specialized functions. In this chapter, we will stress the structures of the macromolecules common to all organisms. Our discussion will emphasize how fundamental principles of chemistry as presented throughout this textbook can contribute to a knowledge of the living state.

28-1 Chemical Structure of Living Matter: An Overview

From one-celled organisms to humans, the living state includes some highly complex forms of matter. About 30 of the known elements occur in measurable concentrations in living matter. Of these, about 25 have functions that are definitely known. Four elements together—oxygen, carbon, hydrogen, and nitrogen—account for 96% of human body mass. Figure 28-1 identifies the elements found in living matter. As shown in Figure 28-2, the complex structures of living matter are synthesized in several stages from a few simple environmental precursors—N_2, H_2O, and CO_2.

In addition to water, which is the most abundant compound in the majority of living organisms, other important constituents are lipids, carbohydrates, proteins, and nucleic acids. These four types of macromolecular substances are the principal topics of this chapter.

The **cell is** the fundamental unit of all life. Cells contain a variety of substructures, such as a nucleus, mitochondria, and chloroplasts (plant cells). Cells combine to form tissues; tissues can be grouped into organs; organs combine into organ systems, and organ systems together form organisms.

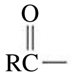
28-2 Lipids

Lipids are best described through their physical properties rather than in precise structural terms. **Lipids** are those constituents of plant and animal tissue that are soluble in low-polarity solvents, such as chloroform, carbon tetrachloride, diethyl ether, and benzene. Many compounds fit this description, but we will discuss only a few of them.

Triglycerides are esters of glycerol (1,2,3-propanetriol) and long-chain monocarboxylic acids (fatty acids). Some common fatty acids are listed in Table 28.1. *Triglyceride* is a common name; the systematic name of the triglycerides is triacylglycerols. *Glycerol* provides the three–carbon backbone, and the fatty acids provide *acyl* groups (in blue below).

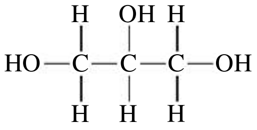
KEEP IN MIND

that in forming an ester, a carboxylic acid loses its —OH group. The group that remains,

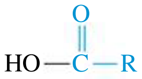


$R\overset{\overset{\displaystyle O}{\|}}{C}-$

is the *acyl* group.



Glycerol

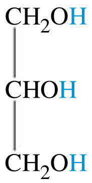


Fatty acid

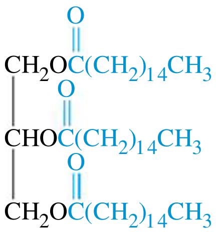
TABLE 28.1 Some Common Fatty Acids

Common Name	IUPAC Name	Formula
Saturated Acids		
Lauric acid	Dodecanoic acid	$C_{11}H_{23}CO_2H$
Myristic acid	Tetradecanoic acid	$C_{13}H_{27}CO_2H$
Palmitic acid	Hexadecanoic acid	$C_{15}H_{31}CO_2H$
Stearic acid	Octadecanoic acid	$C_{17}H_{35}CO_2H$
Unsaturated Acids		
Oleic acid	9-Octadecenoic acid	$C_{17}H_{33}CO_2H$
Linoleic acid	9,12-Octadecadienoic acid	$C_{17}H_{31}CO_2H$
Linolenic acid	9,12,15-Octadecatrienoic acid	$C_{17}H_{29}CO_2H$
Eleostearic acid	9,11,13-Octadecatrienoic acid	$C_{17}H_{29}CO_2H$

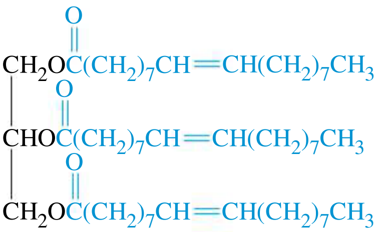
If all acyl groups are the same, the triglyceride is a *simple* triglyceride; otherwise it is a *mixed* triglyceride. In naming a triglyceride, the name *glyceryl* is written first, followed by a compound name for the three acyl groups. The acyl groups are named in the order in which they are attached to the glyceryl backbone. The first two names are given an *o* ending and the third, an *ate* ending. If all acyl groups are the same, only the ending *ate* is used, together with the prefix *tri*.



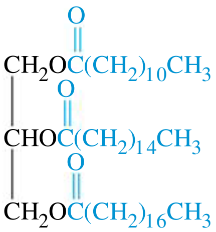
Glycerol



Glyceryl tripalmitate
Tripalmitin
(a simple triglyceride; a fat)

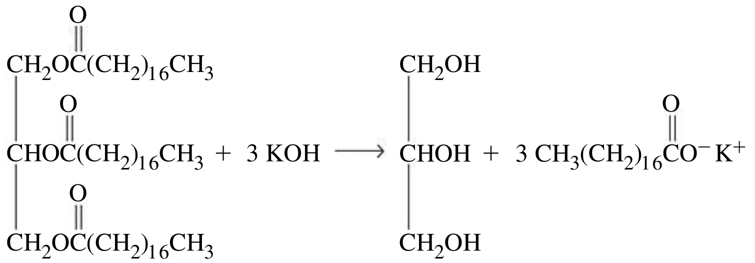


Glyceryl trioleate
Triolein
(a simple triglyceride; an oil)



Glyceryl lauropalmitostearate
(a mixed glyceride)

Triglycerides can be *hydrolyzed* in alkaline solution to produce glycerol and salts of the fatty acids. The hydrolysis process is called **saponification**, and the salts are commonly known as **soaps**. For example, the hydrolysis of tristearin with aqueous KOH gives glycerol and the soap potassium stearate



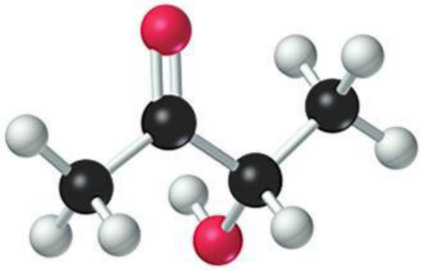
$$\begin{array}{l}\mathrm{CH_2O\overset{O}{\overset{\|}{C}}(CH_2)_{16}CH_3}\\ \quad|\\ \mathrm{CHO\overset{O}{\overset{\|}{C}}(CH_2)_{16}CH_3}\\ \quad|\\ \mathrm{CH_2O\overset{O}{\overset{\|}{C}}(CH_2)_{16}CH_3}\end{array} + 3\,\mathrm{KOH} \longrightarrow \begin{array}{l}\mathrm{CH_2OH}\\ \quad|\\ \mathrm{CHOH}\\ \quad|\\ \mathrm{CH_2OH}\end{array} + 3\,\mathrm{CH_3(CH_2)_{16}\overset{O}{\overset{\|}{C}}O^-\,K^+} \qquad \textbf{(28.1)}$$

Tristearin Glycerol Potassium stearate (a soap)

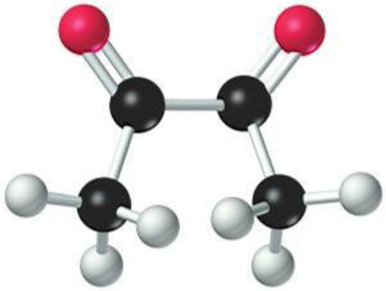
The cleansing action of soaps was described in Section 21-2 (page 932).

Fats and oils are both triglycerides (*glyceryl esters*), but differ from each other by the nature of the acid components in the triglycerides. **Fats** are glyceryl esters in which *saturated* fatty acid components predominate; they are solids at room temperature. **Oils** have a predominance of *unsaturated* fatty acids and are liquids at room temperature. The compositions of fats and oils are variable and depend not only on the particular plant or animal species involved but also on dietary and climatic factors. Some common fats and oils are listed in Table 28.2.

When pure, fats and oils are colorless, odorless, and tasteless. The characteristic colors, odors, and flavors commonly associated with fats and oils come from other organic substances present as impurities. The yellow color of butter is that of β-carotene (a yellow pigment also found in carrots and marigolds). The taste of butter is attributed to 3-hydroxy-2-butanone and diacetyl.



3-Hydroxy-2-butanone



Diacetyl

TABLE 28.2 Some Common Fats and Oils

	Component Acids,[a] % by Mass					
	Saturated			Unsaturated		
Lipid	Myristic	Palmitic	Stearic	Oleic	Linoleic	Linolenic
Fats						
Butter	7–10	24–26	10–13	28–31	1–3	0.2–0.5

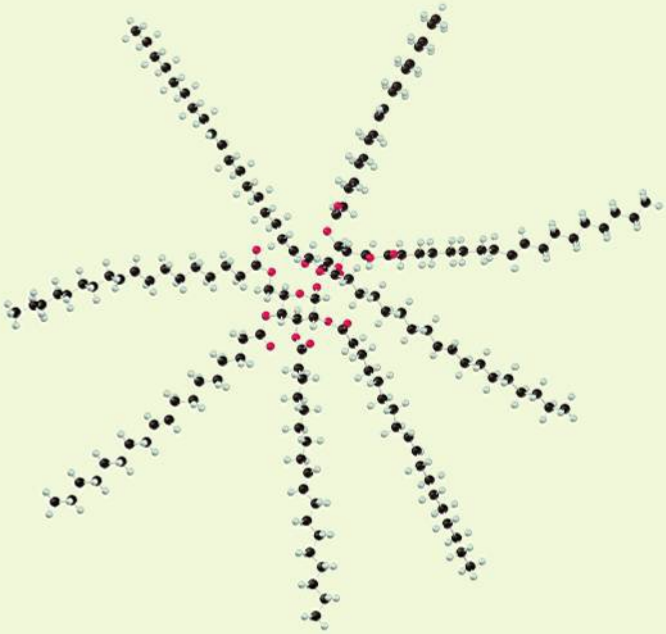
Safflower	—	6–7	2–3	12–14	75–80	0.5–1.5

[a] The formulas of the individual acids are listed in Table 28.1.

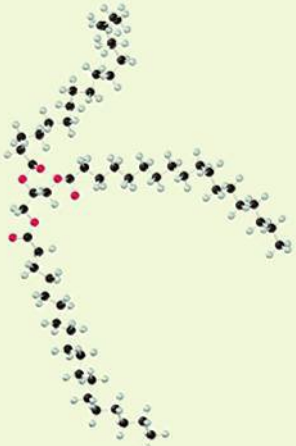
28-1 ARE YOU WONDERING...

What "calorie-free" fats are?

In olestra, an ester of fatty acids and sucrose, the sucrose molecule takes the place of glycerol as the backbone of the ester. When olestra is burned in a bomb calorimeter, the liberated heat is comparable to that obtained in the combustion of other oils and fats. So, in this sense, olestra is *not* calorie free. However, the sucrose backbone of the olestra molecule can bond with six, seven, or eight acyl groups instead of the three acyl groups in a triglyceride, as shown below. Human enzymes cannot break down this bulky molecule, and so it is not digested. It is in this sense that it is calorie free.



Olestra



Triglyceride

Mazola
Sweet Unsalted Premium
Mazola
Rich in CORN OIL
Margarine
100% PURE
Mazola
CORN OIL
Margarine

▲ Corn oil has the approximate composition listed in Table 28.2. Hydrogenation converts some of the unsaturated to saturated fatty acid components—the primary change required in making margarine from vegetable oils.

Unsaturated fats and oils can be converted to saturated ones by the catalytic addition of hydrogen (hydrogenation). Thus, oils or low-melting fats are changed to higher-melting fats. These higher-melting fats, when mixed with skim milk, fortified with vitamin A, and artificially colored, are known as *margarines*. Unsaturation in a fat or an oil is also removed when the fat or an oil decomposes. Edible fats and oils both hydrolyze and cleave at the double bonds by oxidation on exposure to heat, air, and light. When this happens, the fat becomes rancid. The low-molecular-mass fatty acids produced by this cleavage have offensive odors, as exhibited by butyric acid in rancid butter. Antioxidants are commonly added to oils used in the high-temperature cooking of potato chips and other foods to retard this oxidative rancidity.

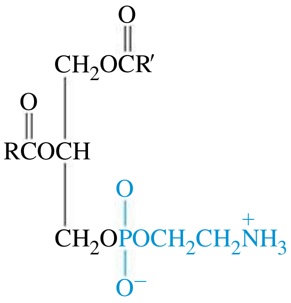
Medical evidence suggests a relationship between a high intake of saturated fats and the incidence of coronary heart disease. For this reason, many diets call for the substitution of unsaturated fatty acids for saturated fatty acids in foods. In general, most mammal fats are saturated, whereas those derived from vegetables and seafood are unsaturated.

28-1 CONCEPT ASSESSMENT

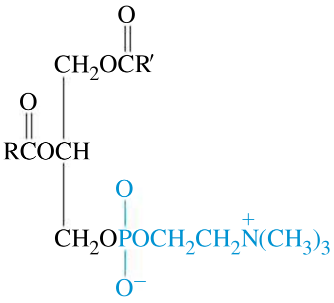
What are the products of the saponification of one mole of glyceryl palmitooleolinolenate with three moles of sodium hydroxide?

Phospholipids

Phospholipids (phosphatides) occur in all animal cells and are especially prevalent in nerve tissue. They are derived from glycerol, fatty acids, phosphoric acid, and a nitrogen-containing base—ethanolamine in a class of phospholipids called *cephalins* and choline in class called *lecithins*. In the following structures, R and R′ are long-chain alkyl groups.



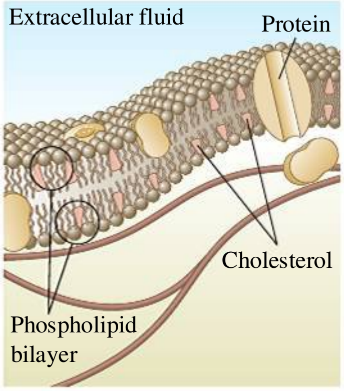
Phosphatidylethanolamine
(a cephalin)



Phosphatidylcholine
(a lecithin)

Like soap molecules, the phospholipids have a hydrophilic head (the phosphate-ethanolamine or phosphate-choline portions shown in blue above) and hydrophobic tails (the two alkyl chains). This enables phospholipids to solubilize and transport fats and oils in aqueous medium, whether this occurs in transporting lipids in the bloodstream or in emulsifying fats and oils in salad dressings.

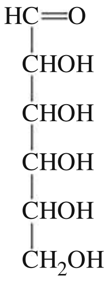
Cell membranes (the outer boundary of all living cells) consist of a bilayer of phospholipids having their hydrophilic heads in an aqueous medium and their hydrophobic portions turned inward into a medium of cholesterol and proteins.



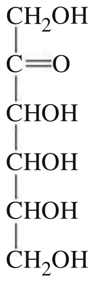
▲ A cell membrane is a bilayer (double layer) of phospholipid molecules with the polar head groups oriented toward the aqueous phase. Other lipid molecules, such as cholesterol, can be embedded in the bilayer. Some proteins are also found in the bilayer; membrane-bound proteins often act as ion pumps by providing a channel for certain ions to pass through.

28-3 Carbohydrates

The literal meaning of "carbohydrate" is hydrate of carbon: $C_x(H_2O)_y$. Thus, sucrose, or cane sugar, $C_{12}H_{22}O_{11}$, is equivalent to $C_{12}(H_2O)_{11}$. A more useful definition is that **carbohydrates** are polyhydroxy aldehydes, polyhydroxy ketones, their derivatives, and substances that yield them on hydrolysis. Carbohydrates that are aldehydes are called aldoses; those that are ketones are called ketoses. A five-carbon carbohydrate is a pentose, a six-carbon one, a hexose, and so on. The structures in the margin are those of two familiar hexoses—glucose and fructose, an aldose and a ketose, respectively.



Glucose

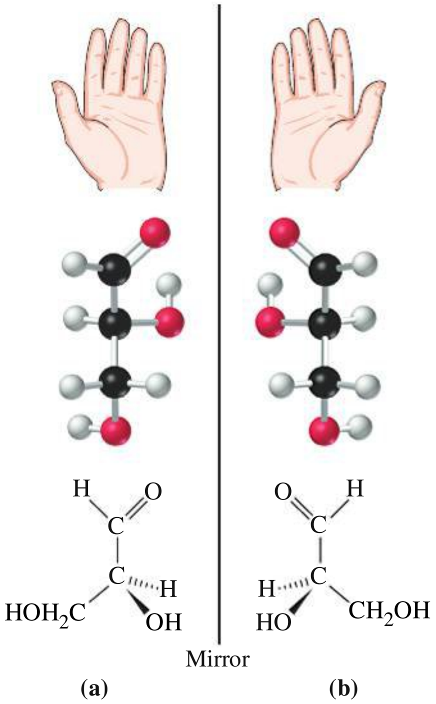


Fructose

The general term for all carbohydrates is *glycoses*. The simplest carbohydrates are collections of individual small molecules of the formula $C_x(H_2O)_y$ and are called **monosaccharides. Oligosaccharides** are larger molecules composed of two to ten monosaccharide units bonded together. Names can be assigned to reflect the actual number of such units present, such as *di*saccharide and *tri*saccharide. Mono- and oligosaccharides are also called **sugars**. **Polysaccharides** contain more than ten monosaccharide units in their basic molecular structure, and many are in the *macromolecular* range. In summary,

Glycoses

- *Monosaccharides*
  - aldoses (aldotriose, aldotetrose, . . .)
  - ketoses (ketotriose, ketotetrose, . . .)
- *Oligosaccharides* (from two to ten monosaccharide units)
  - disaccharides (e.g., sucrose)
  - trisaccharides (e.g., raffinose)
  - and so on.
- *Polysaccharides* (more than ten monosaccharide units)
  - (e.g., starch and cellulose)



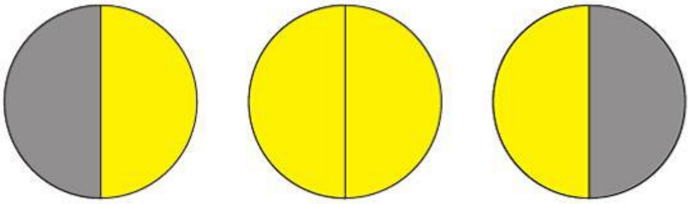
▶ FIGURE 28-3
Optical isomers of glyceraldehyde
The structure in **(a)** is not superimposable on **(b)**, just as a right hand and a left hand are not superimposable.

The simplest glycose is 2,3-dihydroxypropanal (glyceraldehyde), an *aldotriose*. As Figure 28-3 illustrates, the central C atom in glyceraldehyde has four different groups attached to it and is therefore chiral. As we have seen in Chapters 24 and 27, such molecules exhibit an interesting form of stereoisomerism—*optical isomerism*. There are *two* nonsuperimposable structures for glyceraldehyde. Such structures are related to each other like a right and a left hand, or like an object and its nonsuperimposable mirror image; they are *enantiomers* (see Section 24-4 and Section 27-3).

▶ The prefixes *dextro* and *levo* are derived from the Latin words *dexter*, meaning right, and *laevus*, meaning left.

Optically active molecules affect plane-polarized light (Fig. 28-4). Interactions between a beam of polarized light and the electrons in an enantiomer cause a rotation of the plane of the polarized light. One enantiomer rotates the plane of polarized light to the right (clockwise) and is said to be **dextrorotatory** (designated +). The other enantiomer rotates the plane of polarized light to the same extent, but to the left (counterclockwise). It is said to be **levorotatory** (designated −). Because of their ability to rotate the plane of polarized light, isomers of these types are said to be *optically active*, and they are called *optical isomers*. Almost all molecules exhibiting optical isomerism possess at least one asymmetric, or chiral, C atom.

The arrangement of groups at an asymmetric C atom is called the **absolute configuration**. We have already described the *R*, *S* system of nomenclature for describing the absolute configuration of chiral centers. The configuration



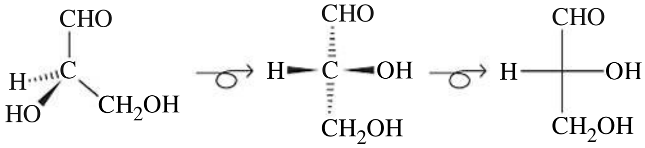
▲ FIGURE 28-4
View through the analyzer prism of a polarimeter (see also Figure 24-9)
The field of view of polarized light from a sodium vapor lamp is split in half. The analyzer prism in the eyepiece has been rotated in the correct direction—clockwise (to the right) or counterclockwise (to the left)—and through the appropriate angle, α (shown in Figure 24-9), when the two halves transmit light of equal intensity (center). For incorrect angles of rotation, one semicircle is darker than the other.

of glyceraldehyde shown in Figure 28-3(a) is (*S*)-glyceraldehyde. The (*R*)-glyceraldehyde is shown in Figure 28-3(b). But which configuration rotates the plane of polarized light in a dextrorotatory (+) sense? Optical rotation studies alone cannot tell us which of the enantiomers rotates the plane of plane-polarized light in a positive sense or a negative sense, because there is no way to assign the *R* or *S* configuration to a particular one of a pair of enantiomers. That is, there is no relationship between the absolute configuration and the sign of the rotation; both must be determined experimentally by independent methods. The assignment of which configuration, *R* or *S*, is the dextrorotary (+) isomer has been achieved using X-ray studies. These methods show that the enantiomer that corresponds to the dextrorotatory (+) isomer has the *R* configuration and is named (*R*)-(+)-glyceraldehyde (Fig. 28-3b). Correspondingly, the levorotatory (−) isomer is found to correspond to the *S* configuration and is named (*S*)-(−)-glyceraldehydes (Fig. 28-3a). It is purely fortuitous that the positive rotation corresponds to the *R* configuration.

The German chemist Emil Fischer studied carbohydrates in the late nineteenth century when techniques for determining the configuration of compounds were not available. Fischer arbitrarily assigned the configuration shown in Figure 28-3b to the dextrorotatory isomer of glyceraldehyde. Fischer designated this configuration D and named the isomer D-(+)-glyceraldehyde; D-(+)-glyceraldehyde is (*R*)-(+)-glyceraldehyde, and L-(−)-glyceraldehyde is (*S*)-(−)-glyceraldehyde. This system, extended to other chiral structures, is called the D, L convention.

We have already seen how to use a dashed and solid wedge line diagram to represent the three-dimensional structure of a molecule such as glyceraldehyde. Drawing these diagrams is not too difficult for compounds containing one or two stereocenters, but the process becomes increasingly cumbersome for compounds having several chiral centers, which carbohydrates often do. In addition to assigning the configuration to (*R*)-(+)-glyceraldehyde, Emil Fischer introduced a convention for representing three-dimensional structures in two-dimensional drawings, now called **Fischer projection formulas**.

The Fischer projections have two aspects to them: The first is how the stereochemistry at a chiral carbon atom is represented in two dimensions, and the second is how the carbon-chain backbone is arranged on the page. First, the bonds between each C atom and its four substituents are drawn in the form of a cross, the central carbon being at the point of intersection. The horizontal lines signify bonds directed toward the viewer; the vertical lines point away. Dashed and solid wedge line structures have to be arranged in this way to allow their conversion into Fischer projections. Consider (*R*)-(+)-glyceraldehyde.



In order to view the molecule with two groups pointing toward us, we imagine the molecule as being picked up by the hydroxyl group and the hydrogen atom and then turned to bring these groups toward us, as shown. The CHO and CH_2OH groups naturally take up positions away from us. The Fischer projection is drawn with the H and OH groups connected by a horizontal line and the CHO and CH_2OH groups joined by a vertical line. Note that the central C atom is not drawn in, but is understood to be at the point of intersection of the lines; including this C atom would make the Fischer projection indistinguishable from a Lewis structure, which contains no stereochemical information.

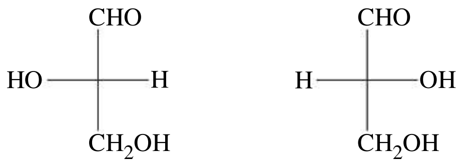
In the Fischer notation, the structural formula is drawn so that the backbone of the molecule is arranged from top to bottom, with the most oxidized portion of the molecule (—CHO) at the top and the least oxidized (—CH_2OH) at the bottom. Attached groups (—H and —OH) are written to the sides. The end

▲ **Emil Fischer (1852–1919)** Fischer was awarded the Nobel Prize in 1902 for his research on the structures of sugars. Later he also elucidated how amino acid molecules join to form proteins.

KEEP IN MIND

that D and L are like *R* and *S* in that they indicate the configuration of a chiral carbon atom, but they do not indicate whether the compound rotates plane-polarized light to the right (+) or to the left (−).

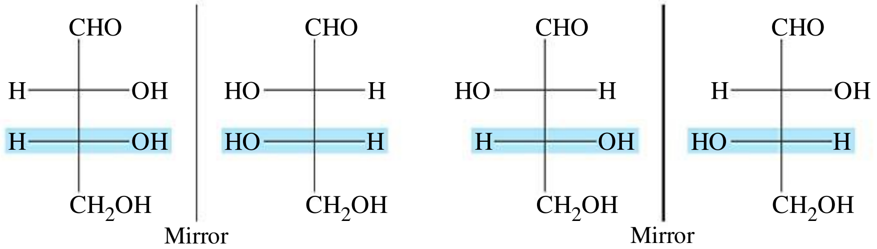
groups of the backbone are considered to extend *behind* the plane of the page, *away* from the viewer. The glyceraldehyde enantiomers are written as



(*S*)-(−) Glyceraldehyde (*R*)-(+)-Glyceraldehyde
(L)-(−) Glyceraldehyde (D)-(+)-Glyceraldehyde

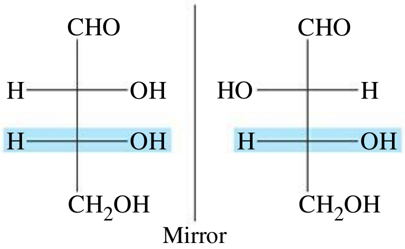
and are used to establish the D, L configuration for other sugars.

The —H and —OH groups on the next-to-last (penultimate) C atom extend in *front* of the page, *toward* the viewer. If the —OH group on this penultimate C atom is to the *right*, the configuration is D. If the —OH is to the left, the configuration is L. This convention is applied below to the four-carbon aldoses, where the penultimate C atom and attached groups are shaded with blue. All D sugars have the same configuration at this penultimate carbon. Figure 28-5 may help you to picture the relationship between a three-dimensional structure and its two-dimensional representation.



D-(−)-Erythrose L-(+)-Erythrose D-(−)-Threose L-(+)-Threose

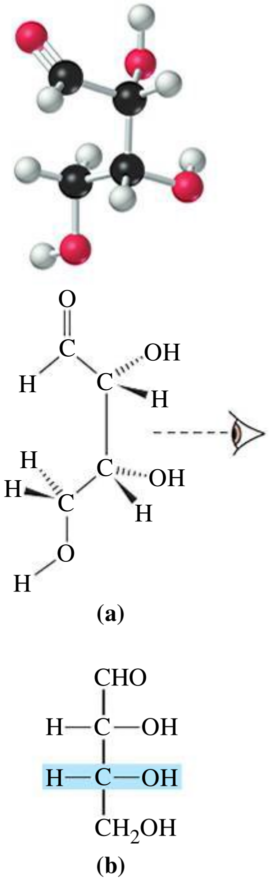
D-Erythrose and L-erythrose are enantiomers, as are D-threose and L-threose. If we compare the configurations of D-erythrose and D-threose, we note that these two molecules are *not* mirror images (see below). On the other hand, they are isomers of each other and both are optically active. Optical isomers that are *not* mirror images of each other are called **diastereomers**.



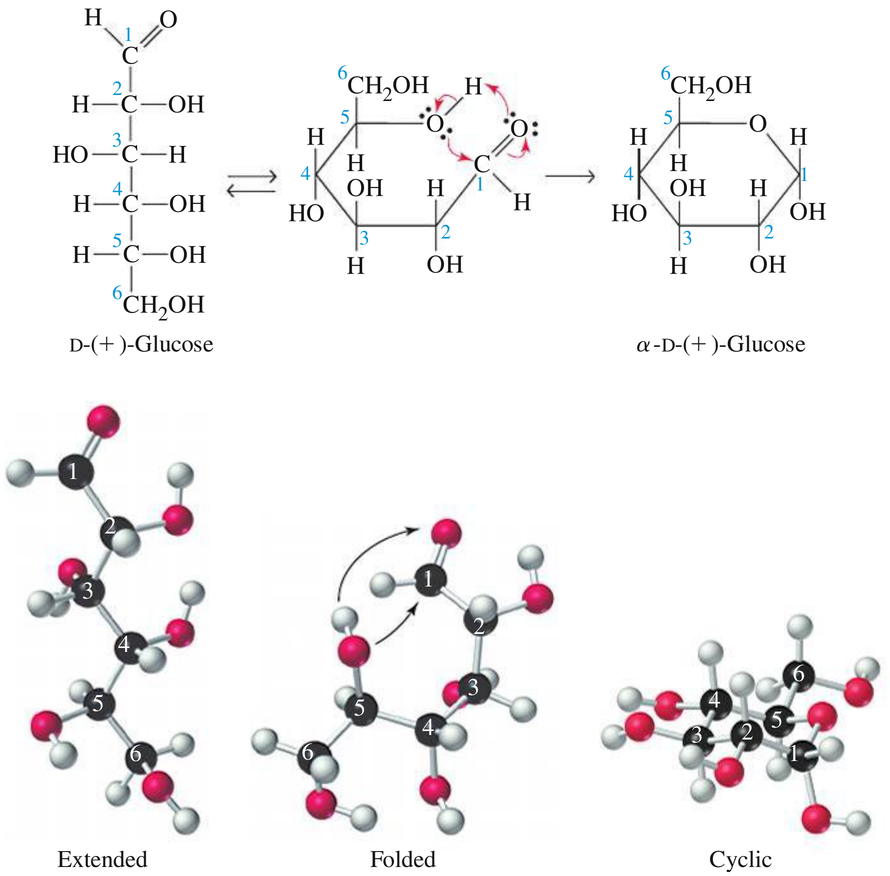
D-Erythrose D-Threose
Not mirror images

Enantiomers differ only in the *direction*, not the extent of their rotation of plane-polarized light. Diastereomers do differ in the extent to which they rotate plane-polarized light. They also differ in physical and chemical properties; for example, they have different solubilities in a particular solvent and react with chemical reagents at different rates.

A mixture of equal amounts of the D and L configurations of a particular substance, called a **racemic mixture**, does not rotate the plane of polarized light either to the left or to the right. The designation DL-erythrose, for example, signifies a racemic mixture. Often, when molecules with chiral centers are synthesized, the product is a racemic mixture. This is because the creation of these centers is a random process, like flipping a coin (an equal probability for heads or tails).



▲ FIGURE 28-5
The structure of D-(−)-erythrose
The three-dimensional structure **(a)** is represented in two dimensions by **(b)**.



◀ FIGURE 28-6
Representation of ring closure in glucose molecule
The straight chain D-(+)-glucose molecule folds back on itself to bring the —OH group on the C-5 atom close to the aldehyde group of the C-1 atom. A proton is transferred, and this is followed by the formation of a six-member ring with an O atom joining the C-1 and C-5 atoms.

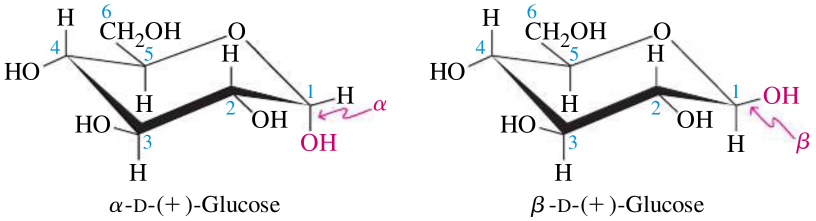
If optically pure isomers are desired, the racemic mixture must be separated into the component enantiomers by a process called *resolution*. Sometimes this is carried out using an enzyme that reacts with one enantiomer but not the other.

Monosaccharides

Of the 16 possible aldohexoses, only three occur widely in nature: D-glucose, D-mannose, and D-galactose. These three sugar molecules exist in a straight-chain form only to a very small extent (less than 0.5% for glucose). The predominant form for each is *cyclic*. In this ring formation, the —OH group of the fifth C atom (C-5) adds to the carbonyl of the C-1 atom and produces a ring composed of five C atoms and one O atom, as illustrated in Figure 28-6. The conformation of the six-member ring is of the chair type (recall Figure 26-12).

When the chain form of a sugar is converted to the ring form, a new chiral (asymmetrical) center is produced at the C-1 atom. There are two possible orientations at this center. In the α form, the —OH at C-1 is *axial* (directed down); in the β form, it is *equatorial* (extends out from the ring). The α and β forms of glucose are pictured in Figure 28-7.

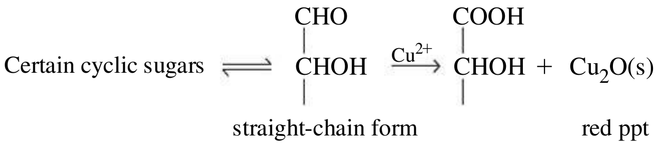
The naming of monosaccharides in the ring form is complicated, but each item in a name conveys precise information. Thus, D-(+)-glucose refers to the straight-chain form of glucose in the D configuration; the (+) indicates this



◀ FIGURE 28-7
α and β forms of D-glucose
In the α form, the —OH group at C-1 (in red) is axial, extending below the chair-like ring. In the β form, the —OH group is equatorial and extends out from the ring.

form is dextrorotatory. The name α-D-(+)-glucose denotes the ring form derived from D-glucose with the α configuration at the C-1 atom.

Monosaccharides such as glucose are known as **reducing sugars**, which means that a sufficient amount of the straight-chain form is in equilibrium with the cyclic form that the sugar engages in an oxidation–reduction reaction with $Cu^{2+}(aq)$. The $Cu^{2+}(aq)$ is reduced to insoluble red Cu_2O, and the aldehyde portion of the sugar is oxidized (to an acid). The test for a reducing sugar is conducted with alkaline copper ion complexed with tartrate (Fehling's solution) or citrate ion (Benedict's solution).



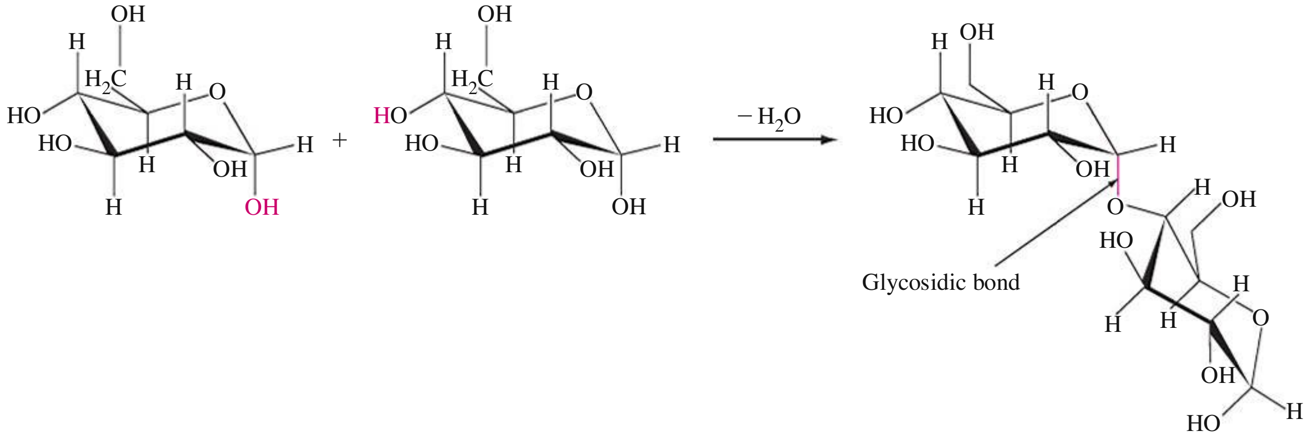
$$\text{Certain cyclic sugars} \rightleftharpoons \underset{\text{straight-chain form}}{\overset{\text{CHO}}{\text{CHOH}}} \xrightarrow{Cu^{2+}} \overset{\text{COOH}}{\text{CHOH}} + \underset{\text{red ppt}}{Cu_2O(s)} \qquad (28.2)$$

28-2 CONCEPT ASSESSMENT

Can a Fischer projection formula be used to represent D-(−)-glucose? Explain.

Disaccharides

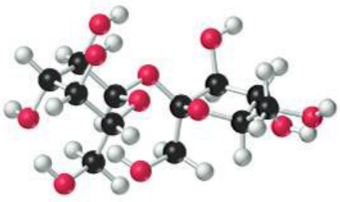
Two monosaccharides can join together by eliminating a H_2O molecule between them—a condensation reaction.



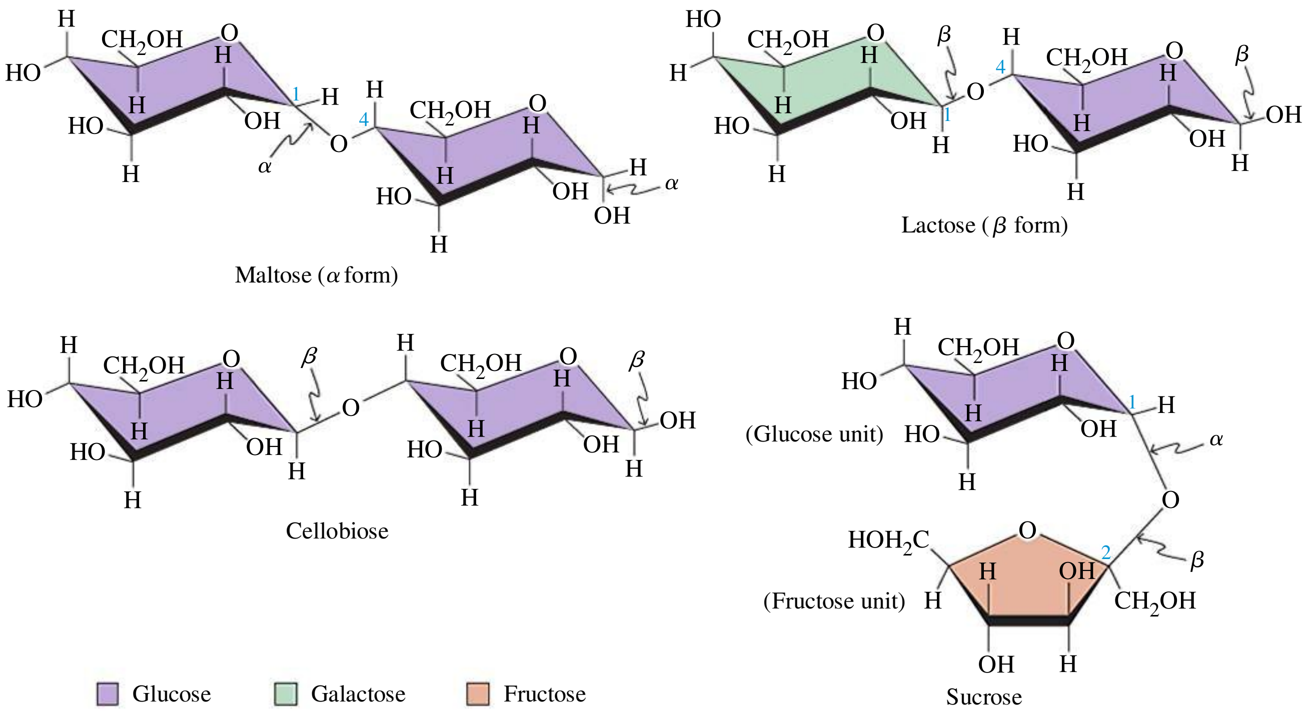
The new bond formed between the two monosaccharides is call a glycosidic bond. This combination of monosaccharides is called a *disaccharide*. In describing a disaccharide, we must consider the identity of the component monosaccharides and whether the configuration of the linkage between the monosaccharides is α or β. The important, naturally occurring disaccharides—maltose, cellobiose, lactose, and sucrose—are presented in Figure 28-8.

In *maltose*, a H atom on the C-1 hydroxyl group of one glucose unit reacts with the hydroxyl group on the C-4 atom of a second glucose unit. The two units are linked in the α manner. Equilibrium is possible between the cyclic and straight-chain forms of maltose, so it is a reducing sugar. Maltose is produced by the action of malt enzyme on starch. In the presence of yeast, maltose undergoes fermentation—first to glucose and then to ethanol and $CO_2(g)$.

Cellobiose can be obtained by the careful hydrolysis of cellulose. It is a glucose-glucose disaccharide with β linkages. *Lactose*, or milk sugar, is naturally present in milk, where its concentration may range from 0 to 7% in different mammals. It is a galactose-glucose disaccharide with β linkages. *Sucrose* is ordinary table sugar (cane or beet sugar). It is a glucose-fructose disaccharide linked 1α, 2β. Neither of the two cyclic sugar units can open up into a chain form, and so sucrose is *not* a reducing sugar.



▲ Sucrose



▲ FIGURE 28-8
Some common disaccharides

Polysaccharides

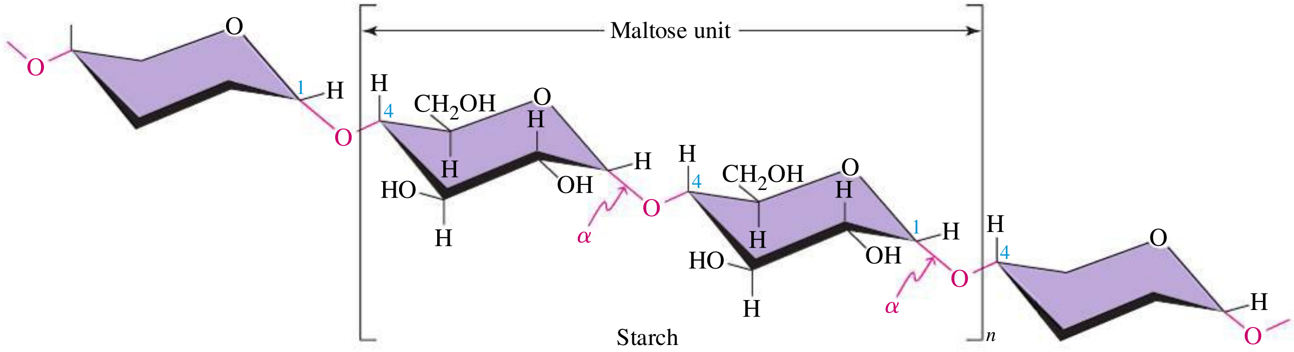
Polysaccharides are composed of monosaccharide units joined into long chains by oxygen linkages. *Starch*, with a molecular mass between 20,000 and 1,000,000 u, is the reserve carbohydrate of many plants and is the bulk constituent of cereals and potatoes. Its structural features are shown in Figure 28-9. *Glycogen* is the reserve carbohydrate of animals; it is stored in the liver and in muscle tissue. It has a higher molecular mass than starch, and the polysaccharide chains are more branched. *Cellulose* is the main structural material of plants. It is the chief component of wood pulp, cotton, and straw. Complete hydrolysis of cellulose produces glucose. Cellulose has a molecular mass between 300,000 and 500,000 u, corresponding to 1800–3000 glucose units. Most animals, including human beings, do not possess the necessary enzymes to hydrolyze β linkages. As a result, they cannot digest cellulose. Certain bacteria in ruminants (cows, deer, camels) and termites can hydrolyze cellulose, allowing them to use it as a food. Termites, as we know, subsist on a diet of wood.

Photosynthesis

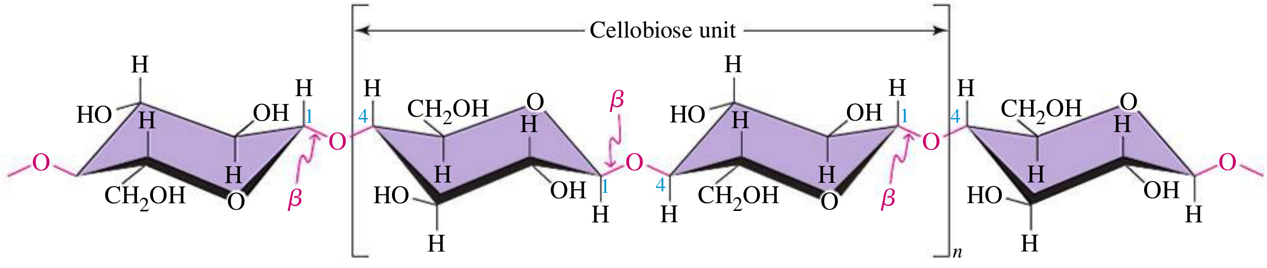
As we have noted in Sections 7-9 and 24-11, the process of photosynthesis involves the conversion by plants of carbon dioxide and water into carbohydrates. Photosynthesis requires the catalyst chlorophyll (see Figure 24-25) and sunlight.

$$n\,\mathrm{CO_2} + n\,\mathrm{H_2O} \xrightarrow[\text{chlorophyll}]{\text{sunlight}} \mathrm{C}_n(\mathrm{H_2O})_n + n\,\mathrm{O_2} \qquad \textbf{(28.3)}$$

Equation (28.3) is greatly oversimplified. The currently accepted mechanism, proposed by Melvin Calvin (Nobel Prize, 1961), involves as many as 100 sequential steps for the conversion of six moles of carbon dioxide to one mole of glucose. The elucidation of this mechanism was greatly aided by the use of carbon-14 as a radioactive tracer. For simplicity, the overall photosynthetic process is divided into two phases: (1) the conversion of solar energy to chemical energy—the light



Starch



Cellulose

▲ FIGURE 28-9
Two common polysaccharides
The linkage between carbon 1 on one ring and carbon 4 on the other ring is commonly designated as 1 → 4. The 1 → 4 linkage between the monosaccharides of starch (α) and cellulose (β) are different. This difference results in cellulose being able to adopt a straighter polymer chain than starch can. This means that more hydrogen bonding occurs between the long cellulose polymer chains, making it stronger for plant structure.

reactions; and (2) the synthesis, promoted by enzymes, of carbohydrates. This latter phase, called the dark reactions, can occur in the absence of light.

Biomass

Biomass is any living matter. An important component of biomass is the organic material produced by photosynthesis, that is, plants or their principal constituents—cellulose, starch, sugars. Plant biomass can be used directly as a fuel, or it may be converted to other gaseous, liquid, or solid materials, which can be used as fuels or chemical raw materials.

Perhaps the best known and most widely used conversion method is the fermentation of sugars to ethanol. Fermentation involves the decomposition of organic matter in the absence of air and through the action of a microorganism.

$$\text{hexose sugar} \xrightarrow{\text{yeast}} 2\,CH_3CH_2OH + 2\,CO_2$$

In North America, the main raw material for the production of ethanol by fermentation is corn.

The conversion of plant material to fossil fuels requires geologic processes and geologic time scales, thereby limiting the future availability of these fuels as energy sources and as raw materials. In principle, most of the compounds now being produced from fossil fuels could be made directly from cellulose. Methanol (wood alcohol) is formed by the destructive distillation (pyrolysis) of wood. Cellulose can be hydrolyzed to glucose and then converted to ethanol by fermentation. Fermentation processes can also be used to produce a series of oxygenated compounds—alcohols and ketones—which can be converted to hydrocarbons. Thus, the entire spectrum of organic chemicals could be produced from the simple molecules CO_2 and H_2O. The required energy would be mostly solar.

Vortex Reactor

28-4 Proteins

When a protein is hydrolyzed by dilute acids, bases, or hydrolytic enzymes, the result is a mixture of α-amino acids. An *amino acid* is a carboxylic acid that also contains an amine group, $-NH_2$; an **α-amino acid** has the amino group on the α carbon atom—the C atom next to the carboxyl group. Thus, **proteins** are high-molecular-mass polymers composed of α-amino acids. Of the known α-amino acids, about 20 have been identified as the building blocks of plant and animal proteins. Some of these amino acids are listed in Table 28.3.

Proteins are the basis of protoplasm and are found in all living organisms. In animals, proteins—as muscle, skin, hair, and other tissue—make up the bulk of

◀ The word *protein* is derived from the Greek word *proteios*, meaning "of first importance" (similar to the derivation of "proton").

TABLE 28.3 Some Common Amino Acids

Name	Symbol	Formula	p*I*[a]
Neutral Amino Acids			
Glycine	Gly	$HCH(NH_2)CO_2H$	6.03
Alanine	Ala	$CH_3CH(NH_2)CO_2H$	6.10
Valine[b]	Val	$(CH_3)_2CHCH(NH_2)CO_2H$	6.04
Leucine[b]	Leu	$(CH_3)_2CHCH_2CH(NH_2)CO_2H$	6.04
Isoleucine[b]	Ileu or Ile	$CH_3CH_2CH(CH_3)CH(NH_2)CO_2H$	6.04
Serine	Ser	$HOCH_2CH(NH_2)CO_2H$	5.70
Threonine[b]	Thr	$CH_3CH(OH)CH(NH_2)CO_2H$	5.6
Phenylalanine[b]	Phe	$C_6H_5CH_2CH(NH_2)CO_2H$	5.74
Methionine[b]	Met	$CH_3SCH_2CH_2CH(NH_2)CO_2H$	5.71
Cysteine	Cys	$HSCH_2CH(NH_2)CO_2H$	5.05
Cystine	$(Cys)_2$	$[SCH_2CH(NH_2)CO_2H]_2$	5.1
Tyrosine	Tyr	$4\text{-}HOC_6H_4CH_2CH(NH_2)CO_2H$	5.70
Tryptophan[b]	Trp		5.89
Proline[c]	Pro		6.21
Acidic Amino Acids			
Aspartic acid	Asp	$HO_2CCH_2CH(NH_2)CO_2H$	2.96
Glutamic acid	Glu	$HO_2CCH_2CH_2CH(NH_2)CO_2H$	3.22
Basic Amino Acids			
Lysine[b]	Lys	$H_2N(CH_2)_4CH(NH_2)CO_2H$	9.74
Arginine	Arg	$H_2NC(=NH)NH(CH_2)_3CH(NH_2)CO_2H$	10.73
Histidine	His		7.58

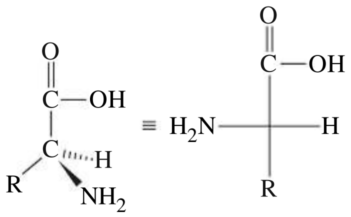
[a] pH of *isoelectric point.*

[b] Essential amino acids. In addition, arginine and glycine are required by the chick, arginine by the rat, and histidine by human infants.

[c] The secondary amino group makes proline an α-*imino* acid. Nevertheless, it is commonly listed with amino acids.

the body's nonskeletal structure. As enzymes, proteins catalyze biochemical reactions; as hormones, they regulate metabolic processes; and as antibodies, they counteract the effect of invading organisms.

Amino Acids Other than glycine ($H_2NCH_2CO_2H$), naturally occurring amino acids are optically active, mostly with an L configuration.

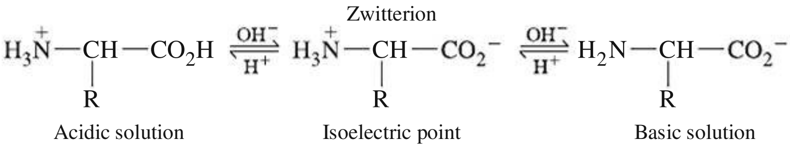


An L-amino acid

The reference structure for establishing the absolute configurations of amino acids is again glyceraldehyde, with the $—NH_2$ group substituting for —OH and $—CO_2H$, for —CHO. The molecule shown above has an L configuration because the $—NH_2$ group appears on the *left*.

Certain amino acids that are required for proper health and growth in human beings cannot be synthesized by the body. These amino acids, which are called the *essential amino acids*, must be ingested as food. Eight amino acids are known to be essential; the case of three others is less certain (see Table 28.3).

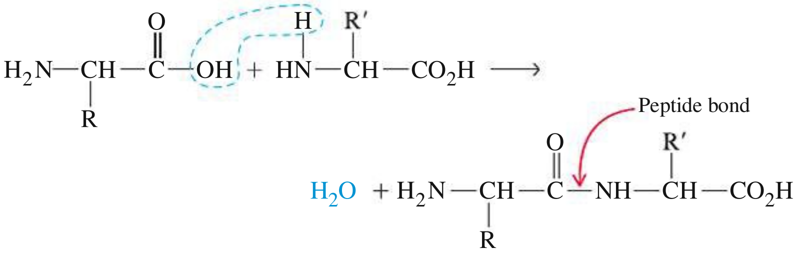
Amino acids are colorless, crystalline, high-melting-point solids that are moderately soluble in water. In a strongly acidic solution (low pH), the amino acid exists as a cation: A proton from solution attaches itself to the unshared pair of electrons on the nitrogen atom in the $—NH_2$ group. In a strongly basic solution (high pH), an anion forms through the loss of protons by the $—CO_2H$ and $—NH_3^+$ groups. At an intermediate isoelectric point, a proton is lost from the $—CO_2H$ but retained by the $—NH_3^+$ group. The product is a dipolar ion, or a **zwitterion**.



$$\underset{\text{Acidic solution}}{H_3\overset{+}{N}—\underset{\displaystyle R}{\underset{|}{CH}}—CO_2H} \underset{H^+}{\overset{OH^-}{\rightleftharpoons}} \underset{\text{Isoelectric point}}{\overset{\text{Zwitterion}}{H_3\overset{+}{N}—\underset{\displaystyle R}{\underset{|}{CH}}—CO_2^-}} \underset{H^+}{\overset{OH^-}{\rightleftharpoons}} \underset{\text{Basic solution}}{H_2N—\underset{\displaystyle R}{\underset{|}{CH}}—CO_2^-} \qquad (28.4)$$

Amino acids are amphoteric. In most amino acids, the acidity of the $—NH_3^+$ group is slightly greater than the basicity of the $—CO_2^-$ group. The largest group of amino acids are close to pH neutral. The pH at which the dipolar structure predominates is called the **isoelectric point**, or p*I* (see Table 28.3). At this pH, the molecule does not migrate in an electric field. At a pH above the p*I*, the molecule migrates to the anode (positive electrode); and below the p*I*, to the cathode (negative electrode). Most basic amino acids have a p*I* well above 7, acidic ones well below 7, and most neutral ones slightly less than 7 (5.7–6.1).

Peptides Two amino acid molecules can be joined by the elimination of a water molecule between them. The amino acids thus joined form a dipeptide. The bond between the two amino acid units is called a **peptide bond**.



$$H_2N—\underset{\displaystyle R}{\underset{|}{CH}}—\overset{\displaystyle O}{\overset{\|}{C}}—OH + \overset{\displaystyle H}{\overset{|}{HN}}—\overset{\displaystyle R'}{\overset{|}{CH}}—CO_2H \longrightarrow H_2O + H_2N—\underset{\displaystyle R}{\underset{|}{CH}}—\overset{\displaystyle O}{\overset{\|}{C}}—NH—\overset{\displaystyle R'}{\overset{|}{CH}}—CO_2H \qquad (28.5)$$

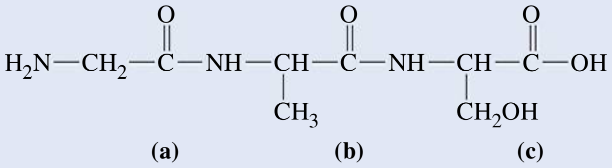
A dipeptide

A tripeptide has three amino acid residues and two peptide linkages. A large number of amino acid units may join to form a **polypeptide**.

The amino acid unit present at one end of a polypeptide chain has a free $—NH_2$ group; this is the N-terminal end. The other end of the chain has a free $—CO_2H$ group; this is the C-terminal end. The polypeptide structure is written with the N-terminal end to the left and the C-terminal end to the right. The base name of the polypeptide is that of the C-terminal amino acid. The other amino acid units in the chain are named as substituents of this acid. Their names change from an *ine* to the *yl* ending. Abbreviations are also commonly used in writing polypeptide names, as illustrated in Example 28-1.

EXAMPLE 28-1 Naming a Polypeptide

What is the name of the polypeptide whose structure is shown below?



$$H_2N—CH_2—\overset{O}{\overset{\|}{C}}—NH—\underset{CH_3}{\underset{|}{CH}}—\overset{O}{\overset{\|}{C}}—NH—\underset{CH_2OH}{\underset{|}{CH}}—\overset{O}{\overset{\|}{C}}—OH$$

Analyze

We can identify the three amino acids in this tripeptide by using Table 28.3: (a) = glycine; (b) = alanine; and (c) = serine. The C-terminal amino acid is serine.

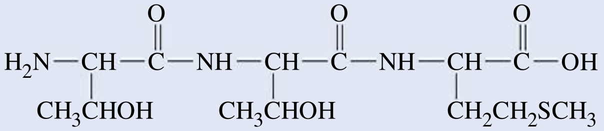
Solve

The name is glycylalanylserine (Gly-Ala-Ser).

Assess

When naming polypeptides, we always begin from the N-terminal and finish at the C-terminal. Remember to replace the *-ine* with *-yl* for all the amino acids except the last one, which retains the *-ine*.

PRACTICE EXAMPLE A: What is the name of the polypeptide shown below?



$$H_2N—\underset{CH_3CHOH}{\underset{|}{CH}}—\overset{O}{\overset{\|}{C}}—NH—\underset{CH_3CHOH}{\underset{|}{CH}}—\overset{O}{\overset{\|}{C}}—NH—\underset{CH_2CH_2SCH_3}{\underset{|}{CH}}—\overset{O}{\overset{\|}{C}}—OH$$

PRACTICE EXAMPLE B: Write the structural formula of the polypeptide serylglycylvaline.

28-3 CONCEPT ASSESSMENT

At pH = 7, what is the most probable charge on the tripeptide molecule, Gly-Ala-Ser, described in Example 28-1?

Amino Acid Sequencing Suppose that a tripeptide is known to consist of the three amino acids: A, B, and C. What is the correct structure: ABC, BAC, . . . ? Can you see that there are six possibilities? For longer chains, of course, the number of possibilities is enormous. Determining the sequence of amino acids in a polypeptide chain is one of the most significant problems in all of biochemistry. The method employed is outlined in Figure 28-10, and the structure of a typical polypeptide, beef insulin, is shown in Figure 28-11.

The distinction between large polypeptides and proteins is arbitrary. It is generally accepted that if the molecular mass is over 10,000 u (roughly 50–75 amino acid units), the substance is a protein. Proteins possess characteristic isoelectric

Amino acid sequence in beef insulin—primary structure of a protein

There are two polypeptide chains joined by disulfide (—S—S—) linkages. One chain has 21 amino acids, and the other 30. In chain A, the Gly at the left end is N-terminal and the Asp is C-terminal. In chain B, Phe is N-terminal and Ala is C-terminal.

points, and their acidity or basicity depends on their amino acid composition. When proteins are heated, treated with salts, or exposed to UV light, profound and complex changes called **denaturation** occur. Denaturation usually brings about a lowering of solubility and loss of biological activity. The frying or boiling of an egg involves the denaturation (coagulation) of the egg albumin, a protein. A hair perm takes advantage of a denaturation process that is reversible. The proteins found in hair (e.g., keratin) contain disulfide linkages (—S—S—). When hair is treated with a reducing agent, these linkages break—a denaturation process. Following this step, the hair is set into the desired style. Next, the hair is treated with a mild oxidizing agent. The disulfide linkages are reestablished, and the hair remains in the style in which it was set.

The Structure of Proteins

Proteins exhibit four levels of structure commonly referred to as primary, secondary, tertiary and quaternary structure. The **primary structure** of a protein refers to the exact sequence of amino acids in the polypeptide chains that make up the protein. But what are the shapes of the long polymeric chains themselves? Are they simply limp and entangled like a plate of spaghetti or is there some order within chains and among chains? The structure or shape of protein segments is referred to as **secondary structure**. In 1951, based on X-ray diffraction studies on polylysine, a synthetic polypeptide, Linus Pauling and R. B. Corey proposed that the orientation of this polypeptide and thus of the protein chain *is helical*. A spiral, helical, or spring-like shape can be either left- or right-handed, but because proteins are composed of l amino acids, their helical structure is right-handed (Fig. 28-12).

EXAMPLE 28-2 Determining the Sequence of Amino Acids in a Polypeptide

A polypeptide, on complete hydrolysis, yielded the amino acids A, B, C, D, and E. Partial hydrolysis and sequence proof gave single amino acids, together with the following larger fragments: AD, CD, DCB, BE, and BC. What must be the sequence of amino acids in the polypeptide?

Analyze

Begin by arranging the fragments in the following manner,

AD
DC
DCB
BE
CB

Solve

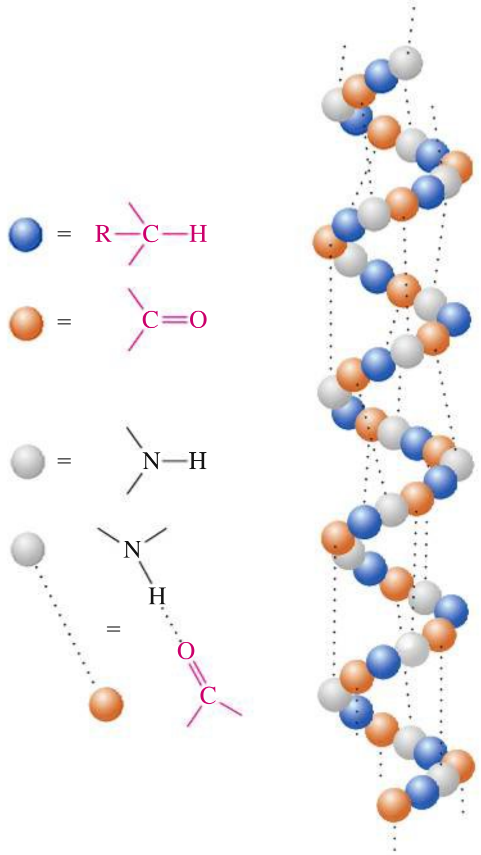
We see that the sequence ADCBE is consistent with the fragments observed.

Assess

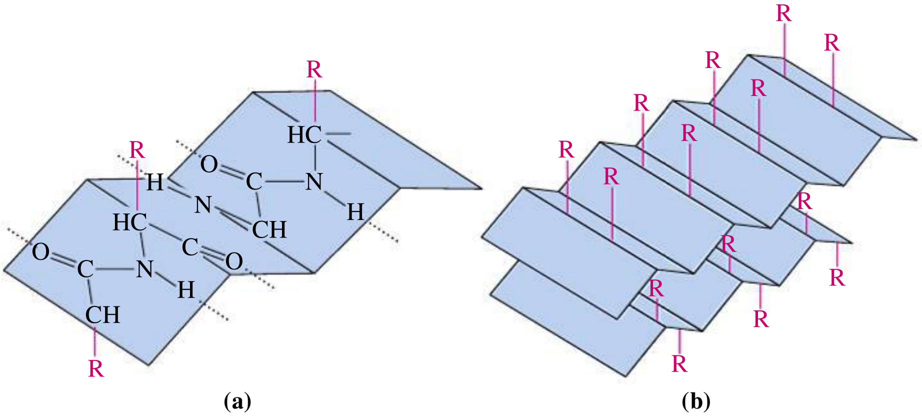
Typically, we write a sequence starting from the N-terminal amino acid and ending at the C-terminal amino acid. Therefore, the sequence EBCDA is also possible because we do not know whether A or E is the N-terminal end of the polypeptide.

PRACTICE EXAMPLE A: On complete hydrolysis, a pentapeptide yields the amino acids Val, Phe, Gly, Cys, and Tyr. Partial hydrolysis yields the fragments Val-Phe, Gly-Cys, Cys-Val-Phe, and Phe-Tyr. Glycine (Gly) is the N-terminal acid. What is the sequence of amino acids in the polypeptide?

PRACTICE EXAMPLE B: On complete hydrolysis, a hexapeptide yields the amino acids Ala, Gly, Ser, Trp, and Val. Partial hydrolysis yields the fragments Val-Trp, Gly-Gly-Ala, Ser-Gly-Gly, and Ala-Val-Trp. Serine (Ser) is the N-terminal acid. What is the sequence of amino acids in the polypeptide?



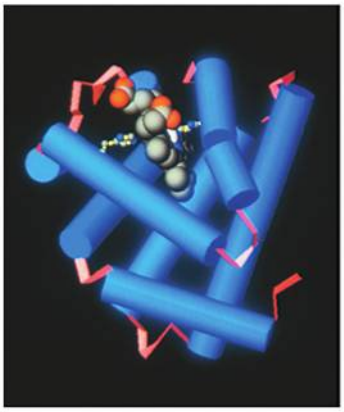
◀ FIGURE 28-12
Secondary structure of a protein—an α helix
The helical structure is stabilized by hydrogen bonds between $-\overset{O}{\overset{\|}{C}}-$groups in one turn and $-\overset{H}{\overset{|}{N}}\cdots$ groups in the next turn above. The bulky R groups are directed outward from the atoms in the spiral.



▶ FIGURE 28-13
Pleated-sheet model of *β*-keratin
(a) A polypeptide chain showing the direction of interpolypeptide hydrogen bonds (other polypeptide chains lie to the left and to the right of the chain shown). Bulky R groups extend above and below the pleated sheet. (b) The stacking of pleated sheets.

Other types of orientations are also possible. For example, *β*-keratin and silk fibroin are arranged in pleated sheets. In these proteins, the side chains extend above and below the pleated sheets, and there is hydrogen bonding between *different* molecules (interpeptide bonding) lying next to each other and about 0.47 nm apart in the same sheet. These sheets are stacked on top of one another about 1.0 nm apart, rather like a pile of sheets of corrugated roofing (Fig. 28-13). Some proteins, such as gamma globulin, are amorphous: They do not have a definite secondary structure.

Many proteins possess additional structural features. For example, rather than being elongated, the coils may be twisted, knotted, and so forth. The final statement regarding the shape of a protein molecule lies in a description of its **tertiary structure**. Because the internal hydrogen bonding between atoms in successive turns of a protein helix is weak, these hydrogen bonds ought to be easily broken. In particular, we should expect them to be replaced by hydrogen bonds to water molecules when the protein is placed in water. That is, the *α* helix should open up and become a randomized structure when placed in water. But experimental evidence indicates that this does not happen, which leads to the conclusion that other forces must be involved in entwining the long *α*-helical chains into definite geometric shapes. The tertiary structure of myoglobin is shown in Figure 28-14. Three types of linkages are involved in tertiary structures as described in Figure 28-15.



▲ FIGURE 28-14
Representation of the tertiary structure of myoglobin

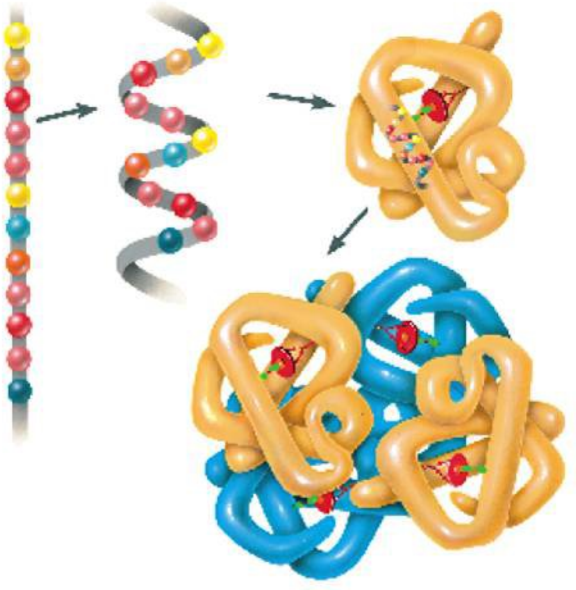
Linkages contributing to the tertiary structure of proteins
(a) *Salt linkages.* Acid–base interactions between different coils. Here, the carboxyl group of an aspartic acid unit on one coil donates a proton to the free amine group of a lysine unit on another. **(b)** *Hydrogen bonding.* Interactions between side chains of certain amino acids, for example, aspartic acid and serine. **(c)** *Disulfide linkages.* Oxidation of the highly reactive thioalcohol group (—SH) of cysteine to a disulfide (—S—S—) can occur (as in beef insulin).

The folding of a polypeptide chain into a tertiary structure is influenced by an additional factor. The hydrophobic hydrocarbon portions of the chains (R groups) tend to pull away from the aqueous medium and retreat to the interior of the structure, leaving ionic groups at the exterior.



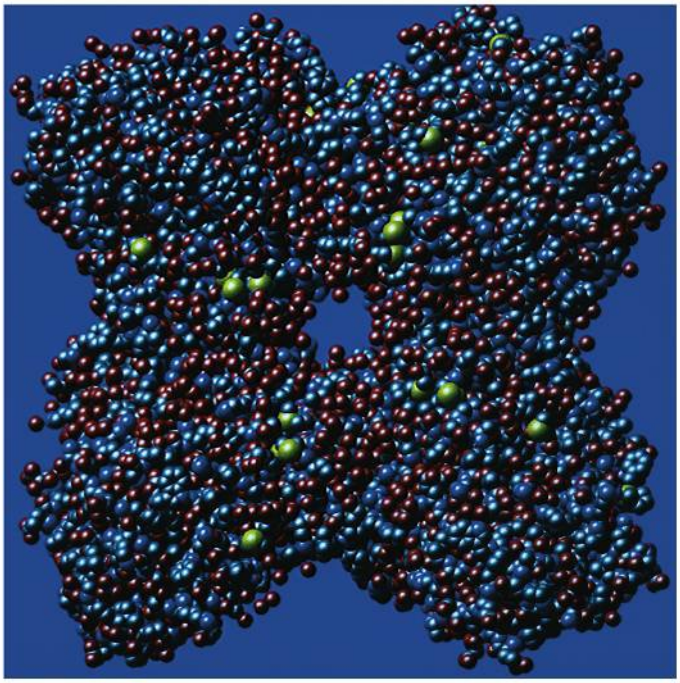
◀ FIGURE 28-16
The four levels of protein structure
Hemoglobin is the oxygen-carrying protein in red blood cells. The iron-containing heme units are shown as red discs. The primary structure of the protein is determined by its amino acid sequence. The secondary structure (α helix) is stabilized through formation of hydrogen bonds, as illustrated in Figure 28-12. The tertiary structure is determined by interactions between the R groups and their surroundings, causing the polypeptide chains to fold in a particular manner. Finally, the quaternary structure is an aggregation of two or more folded chains—four chains in the case of hemoglobin. Not all proteins have a quaternary structure.

The hemoglobin molecule consists of four separate polypeptide chains or subunits. The arrangement of these four subunits constitutes a still higher order of structure referred to as the **quaternary structure**. The levels of protein structure in hemoglobin, from primary to quaternary, are depicted in Figure 28-16.

Even minor changes in the structure of a protein can have profound effects. Hemoglobin contains four polypeptide chains; two chains are labeled α with 141 residues and two are labeled β with 146 residues. The substitution of valine for glutamic acid at one site in two of these chains gives rise to the sometimes fatal blood disease known as sickle-cell anemia. The altered hemoglobin has a reduced ability to transport oxygen through the blood, although it does seem to provide some defense against malaria.

28-4 CONCEPT ASSESSMENT

Polypeptides can fold into helical coils. Would you also expect polysaccharides to form helical coils? Explain.



◀ A computer image of the three-dimensional structure of ribulose-1, 5-biphosphate carboxylase-oxygenase (RuBisCo), which consists of 37,792 atoms. This structure was elucidated in 1988, after an 18-year effort. RuBisCo is the most abundant protein on Earth. Its estimated annual worldwide production by plants is 4×10^{13} g (40 million tons). RuBisCo is the enzyme that initiates the process of photosynthesis.

28-5 Aspects of Metabolism

Although living organisms differ markedly in appearance, there is a striking similarity in the chemical reactions of their life processes. We refer to the totality of these reactions as **metabolism**. Metabolic reactions in which substances are broken down are referred to as *catabolism*. Metabolic reactions in which more complex substances are synthesized from simpler ones are called *anabolism*. Reactions having $\Delta G > 0$ are said to be *endergonic*, and those with $\Delta G < 0$ are *exergonic*. The substances involved in metabolism are called *metabolites*. Metabolism is a complex subject that we can outline only briefly. The discussion that follows centers on the summary of metabolism given in Figure 28-17.

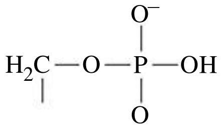
(a) *Fatty acid section*. Fatty acids are degraded two C atoms at a time. Acetyl units enter into the citric acid cycle (c) as acetyl CoA. **(b)** *Glycolysis section (Embden–Meyerhof pathway)*. These reactions are anaerobic (no oxygen required). Carbohydrates are degraded to the six-carbon sugar glucose, and then to the three-carbon triose-P (glyceraldehyde-3-phosphate). Next, the three-carbon acid pyruvic acid is formed from triose-P. Pyruvic acid loses a molecule of CO_2, yielding the two-carbon acetyl unit, which combines with coenzyme A (CoA) to form acetyl CoA. **(c)** *Citric acid cycle* (*Krebs cycle*). A two-carbon acetyl unit from acetyl CoA joins with the four-carbon oxalacetate unit to produce the six-carbon tricarboxylic acid citric acid (designated here as citrate). A two-step conversion to isocitrate occurs, followed by the loss of a molecule of CO_2 and formation of the five-carbon α-ketoglutarate. Another CO_2 molecule is lost in the formation of succinyl CoA. The remainder of the cycle involves a succession of four-carbon acids leading to oxaloacetate. The oxaloacetate regenerated at the end of the cycle now joins with another acetyl unit, and the cycle is repeated. The overall change occurring in the cycle is that a two-carbon acetyl unit enters the cycle and two molecules of CO_2 leave.

Carbohydrate Metabolism

Starch is the principal source of energy for humans and other animals. Digestion of starch begins in the mouth with the action of salivary enzymes, the amylases. Starch is converted to maltose and polysaccharides known as dextrins. This process continues briefly in the stomach (until the enzymes are denatured by the acid present), and the maltose and polysaccharides pass into the small intestine. Here, amylase from the pancreas completes the conversion of polysaccharides to maltose, and the enzyme *maltase* converts the maltose to glucose. Glucose is absorbed through the wall of the small intestine into the bloodstream and distributed to other organs.

Glucose is ultimately oxidized to carbon dioxide and water, with the liberation of energy. The principal intermediate in this process is glucose-6-phosphate (glucose-6P). Once formed, glucose-6P may be converted to glycogen (a polysaccharide stored in the liver), revert back to glucose, or be metabolized. The major metabolic route (Fig. 28-17) involves the anaerobic (absence of air) glycolysis pathway, followed by an aerobic cycle, the citric acid cycle.

◀ In glucose-6-phosphate, a phosphate group replaces the —OH group on the C-6 atom of the cyclic glucose molecule (see Figure 28-7).

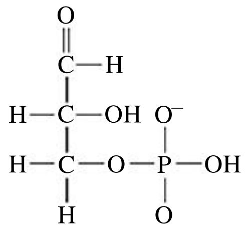


$$H_2C{-}O{-}\overset{\displaystyle O^-}{\underset{\displaystyle O}{P}}{-}OH$$

Lipid Metabolism

The digestion of fats and oils occurs in the small intestine through the action of a combination of lipase enzymes. The products of this enzyme hydrolysis are glycerol, mixtures of mono- and diglycerides, and fatty acids. These are absorbed into the bloodstream through the wall of the intestine. Glycerol is converted to glyceraldehyde-3-phosphate (triose phosphate) and joins into the glucose metabolic route previously described. Fatty acids are oxidized to carbon dioxide and water, with the release of energy, in a series of reactions known as β oxidation. In this process, oxidation occurs at the β carbon atom of a fatty acid, followed by cleavage. Thus, two-carbon pieces (acetic acid) are split off. The process also requires coenzyme A (CoA). For example, with palmitic acid, $C_{15}H_{31}COOH$, the process is repeated seven times, with the formation of eight molecules of acetyl CoA, which enter the Krebs cycle (Fig. 28-17).

◀ The structure of glyceraldehyde-3-phosphate is



Protein Metabolism

In the stomach, HCl(aq) and the enzyme *pepsin* hydrolyze about 10% of the amide linkages in proteins and produce polypeptides in the molecular mass range of 500 to several thousand atomic mass units. In the small intestine, peptidases such as trypsin and chymotrypsin (from the pancreas) cleave the polypeptides into very small fragments. These fragments are then acted on by aminopeptidase and carboxypeptidase. The resulting free amino acids pass through the wall of the intestine, into the bloodstream, and to all the cells of the body, where they are the building blocks of proteins. Protein synthesis is directed by the nucleic acids DNA and RNA (page 1292).

Energy Relationships in Metabolism

The fundamental agents involved in energy transfers from exergonic to endergonic reactions are **adenosine *di*phosphate (ADP)** and **adenosine *tri*phosphate (ATP)**. The following equation represents the conversion of one mole of ATP to one mole of ADP.

$$ATP^{4-} + H_2O \longrightarrow ADP^{3-} + HPO_4{}^{2-} + H^+ \qquad \Delta G^{\circ\prime} = -32.4\text{ kJ} \qquad \textbf{(28.6)}$$

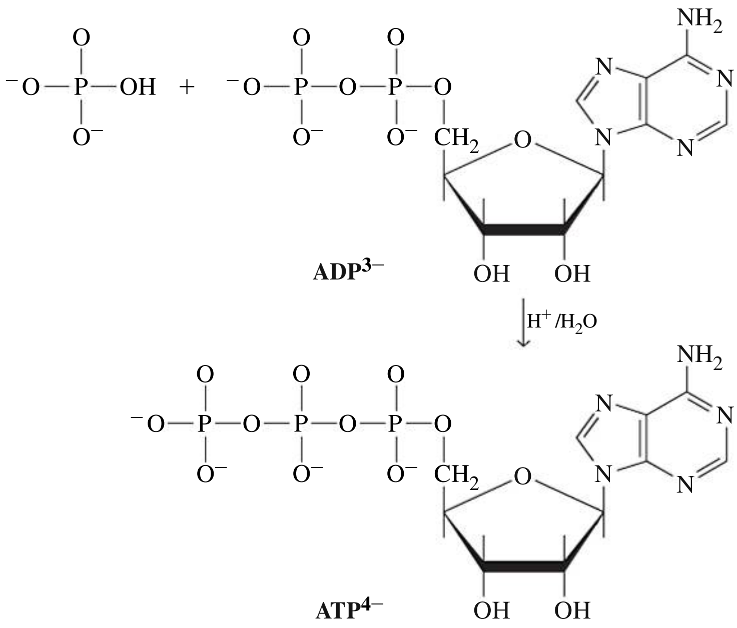
Figure 28-18 represents the reverse of reaction (28.6).

The energy released in the oxidation of foods is picked up by ADP, which is converted to ATP. Enzymes catalyze each step in the overall conversion. The oxidation of one mole of glucose to CO_2 and H_2O is accompanied by the conversion of 38 mol ADP to 38 mol ATP. These two processes are represented below.

$$C_6H_{12}O_6 + 6\,O_2 \longrightarrow 6\,CO_2 + 6\,H_2O \quad \Delta G^\circ = -2880\text{ kJ}$$
$$38 \times \{ADP^{3-} + HPO_4{}^{2-} + H^+ \longrightarrow ATP^{4-} + H_2O\} \quad \Delta G^{\circ\prime} = 38 \times 32.4\text{ kJ} = 1230\text{ kJ}$$

◀ Additional thermodynamic aspects of ADP/ATP conversions are discussed in the Focus On feature for Chapter 19, *Coupled Reactions in Biological Systems*, on the MasteringChemistry site (www.masteringchemistry.com).

▶ Based on the discussion of the expanded valence shell (page 419), we represent all the P-to-O bonds in Figure 28-18 as single bonds. Sometimes these structures are written with one P-to-O double bond in each phosphate unit.



▲ FIGURE 28-18
Conversion of ADP to ATP
The H^+ ion entering into the reaction and the H_2O molecule produced are shown beside the main reaction arrow.

Thus, of the 2880 kJ of energy released in the oxidation of one mole of glucose, 1230 kJ of energy is stored in the high-energy bonds of ATP. The efficiency of this energy storage is $(1230/2880) \times 100\% = 43\%$. That is, nearly half of the energy released in carbohydrate metabolism is stored in the human body for later use. This is a much more efficient use of energy than in an internal combustion engine, for example. If the metabolism of glucose occurred in a single step, with just one mole of ADP converted to one mole of ATP, the efficiency would drop to $(32.4/2880) \times 100\% = 1.1\%$. So we can see why the metabolism of sucrose is such a complex, multistep process.

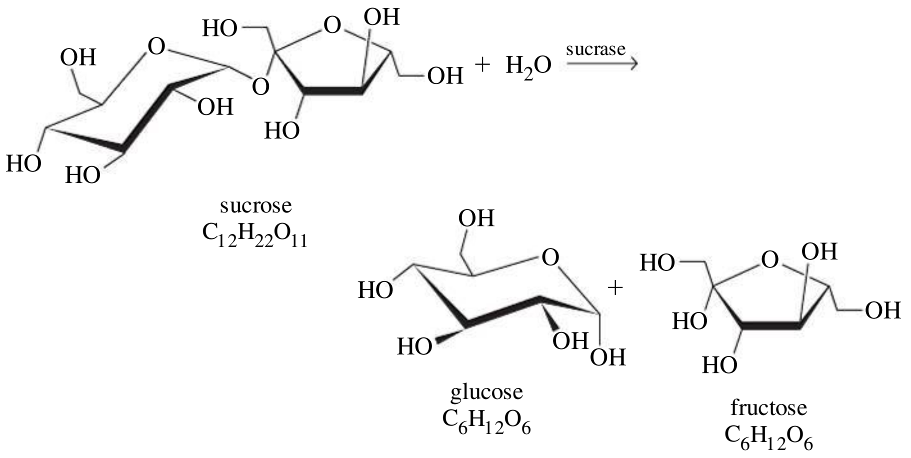
Enzymes

An **enzyme** is a biological catalyst that contains protein. Enzymes are specific for each biological transformation and catalyze a reaction without requiring a change in temperature or pH. Originally, enzymes were assigned common or trivial names, such as pepsin and catalase. Present practice, however, is to name them after the processes they catalyze, usually employing an *ase* ending.

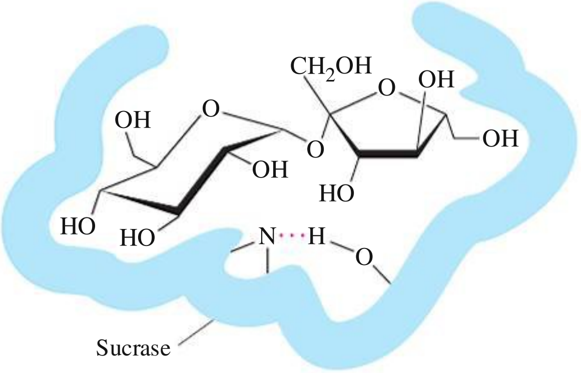
A model for enzyme action was introduced in the discussion of enzyme kinetics in Section 14-11. According to this model, an enzyme can exert its catalytic activity only after combining with the reacting substance, the *substrate*, to form a complex. The site on the enzyme where the substrate bonds is called the *active site*; some enzymes have more than one active site. Reaction of the substrate (S) with the enzyme (E) to form a complex (ES) permits the reaction to proceed via a path of lower activation energy than the noncatalyzed path. When the complex decomposes, products (P) are formed and the enzyme is regenerated.

$$E + S \rightleftharpoons ES \longrightarrow E + P$$

One example is the hydrolysis of sucrose. Recall from Figure 28-8 that sucrose is a disaccharide of glucose and fructose.



The first step is the binding of sucrose to the active site of the enzyme sucrase, as illustrated in Figure 28-19. When the sucrose is in the active site of the enzyme, a number of chemical processes can take place. For example, a proton can be transferred from the sucrase to the glucose, which causes the active site of the sucrase to open up, causing the C—O bond joining fructose and glucose to weaken. The transfer of a proton from an amino acid side chain of the sucrase molecule may destroy hydrogen bonding within the enzyme and cause it to open up; this process stretches the sucrose molecule by pulling at each end, as suggested in Figure 28-20. In this distorted form, the C—O of the disaccharide is highly susceptible to attack by a water molecule. Figure 28-21 shows that after this reaction, glucose and fructose are formed and the proton is transferred back to the sucrase, which causes the active site to return to its original



◀ FIGURE 28-19

state. The smaller fructose and glucose molecules leave the active site, and the enzyme is ready to go again.

Enzymes such as sucrase do not contain metal ions, but almost a third of known enzymes do. One enzyme with a metal ion in the active site is carboxypeptidase, a metalloenzyme active in the digestion of proteins into individual amino acids. In the process, each peptide bond between amino acids is cleaved. A water molecule is broken apart, the H and OH are added to the ends of the polypeptide chain, and an amino acid is released. Hydrolysis reactions of this type are the reverse of condensation reactions.

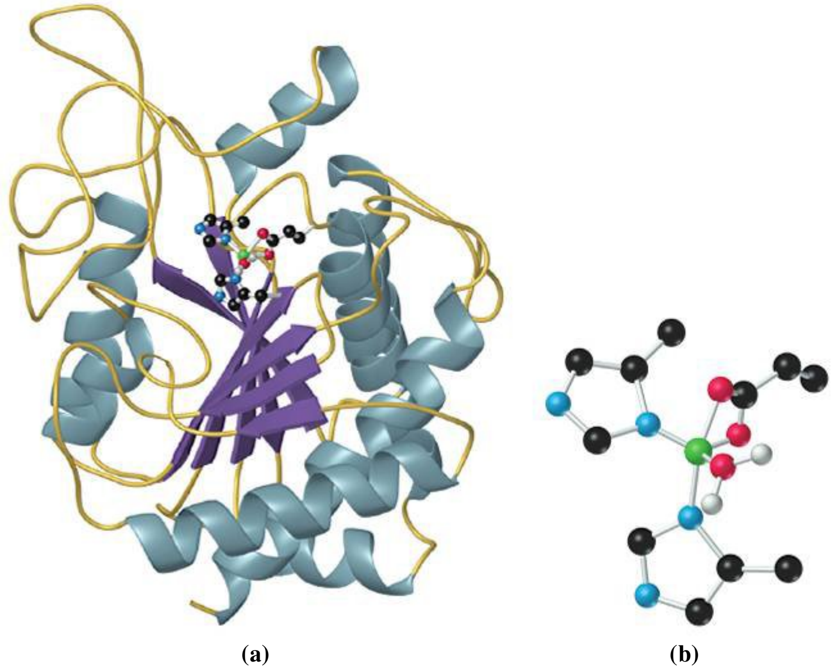
Carboxypeptidase cleaves amino acids one at a time, starting from the carboxyl end of the substrate protein. The enzyme consists of a single polypeptide chain containing 307 amino acids and a single Zn(II) ion. As shown in Figure 28-22, the metal ion is located in a cleft in the molecule, held in place by coordination to three amino acids—two histidines and one glutamic acid. The Zn(II) ion adopts an approximate tetrahedral geometry with the fourth coordination site occupied by a water molecule.

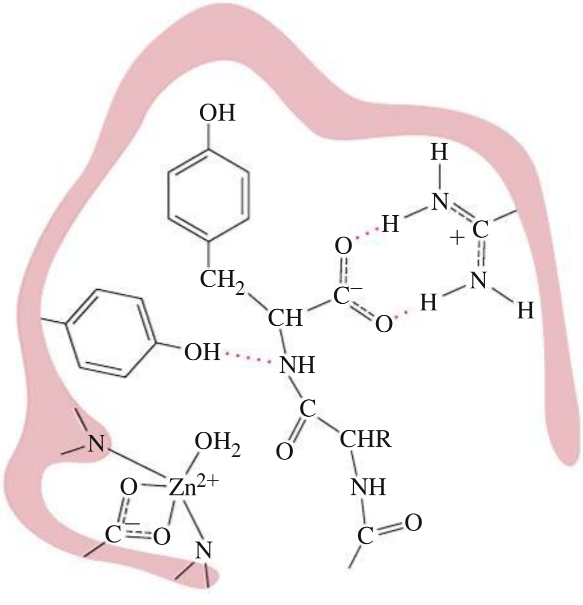


◀ FIGURE 28-22
Structure of carboxypeptidase
(a) In this illustration, the secondary structure of the helices (blue), pleated sheets (purple), and nonspecific secondary structure (yellow) combine to give a visualization of the overall tertiary structure of carboxypeptidase. **(b)** Coordination of the Zn(II) ion, dark green sphere, in the active site.

During the hydrolysis of a protein by carboxypeptidase, the protein substrate binds in the active site of the enzyme, as suggested by Figure 28-23. The substrate is held near the zinc center by hydrogen bonding to several amino acids in the cleft. The details of the mechanism have not been conclusively determined, except that it is known that it is the water coordinated to the Zn(II) that is used in the cleavage of the peptide bond. The proximity of the peptide linkage to the highly polarized water molecule coordinated to the Zn(II) ion permits the cleavage of the peptide bond and release of an amino acid.

The optimum temperature for enzyme activity is about 37 °C (98 °F) for enzymes present in warm-blooded animals. Above this temperature, enzyme activity declines as the secondary and tertiary structures are disrupted and the active site is distorted.

The two enzymes described here provide only a glimpse of the fascinating chemistry involved in the action of enzymes, which is currently a very active area of research.



◀ FIGURE 28-23

28-6 Nucleic Acids

Lipids, carbohydrates, and proteins together with water constitute about 99% of most living organisms. The remaining 1% includes compounds of vital importance to the existence of life. Among these are the **nucleic acids**, which carry the information that directs the metabolic activity of cells. The two nucleic acids are **DNA**, or **deoxyribonucleic acid**, and **RNA**, or **ribonucleic acid**.

DNA is found in the cell nucleus on rodlike structures called chromosomes, which also contain protein. DNA contains the hereditary information that is passed from generation to generation. At specific locations along the chromosomes are *genes*, which are DNA sequences that control the production of a protein chain. This protein chain can manifest as a trait but also as a functional unit in the cell.

Figure 28-24 shows the chemical constituents of DNA and RNA. DNA is made up of the pentose sugar 2-deoxyribose, the purine bases adenine and

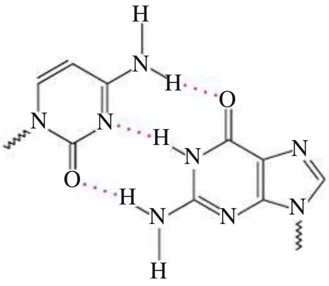
▲ FIGURE 28-24
Constituents of nucleic acids
Tracing the hydrolysis reactions in the reverse direction, the combination of a pentose sugar and a purine or a pyrimidine base yields a nucleoside. A nucleoside in combination with phosphoric acid yields a nucleotide. A nucleic acid is a polymer of nucleotides. If the sugar is 2-deoxyribose and the bases are A, G, T, and C, the nucleic acid is DNA. If the sugar is ribose and the bases are A, G, U, and C, the nucleic acid is RNA. (The term "2-deoxy" means without an O atom on the second C atom.)

guanine, and the pyrimidine bases cytosine and thymine. RNA differs in that it contains ribose instead of deoxyribose, and the base uracil instead of thymine. Both DNA and RNA contain phosphate groups. The combination of a pentose sugar and a purine or pyrimidine base is called a *nucleoside*. The combination of a nucleoside and a phosphate group is called a *nucleotide*. A DNA molecule is made up of two strands of nucleotides held together by hydrogen bonds and twisted into a helix. The figure in the margin illustrates the hydrogen bonding between purine and pyrimidine bases. RNA is generally single stranded but folds back on itself to give helical structures or other hydrogen bonded structures. Figure 28-25 shows a portion of a nucleic acid chain and how the constituents are joined by phosphate groups. If the sugar is 2-deoxyribose and the bases are adenine (A), guanine (G), thymine (T), and cytosine (C), the nucleic acid is DNA. If the sugar is ribose and the bases are adenine (A), guanine (G), uracil (U), and cytosine (C), the nucleic acid is RNA.

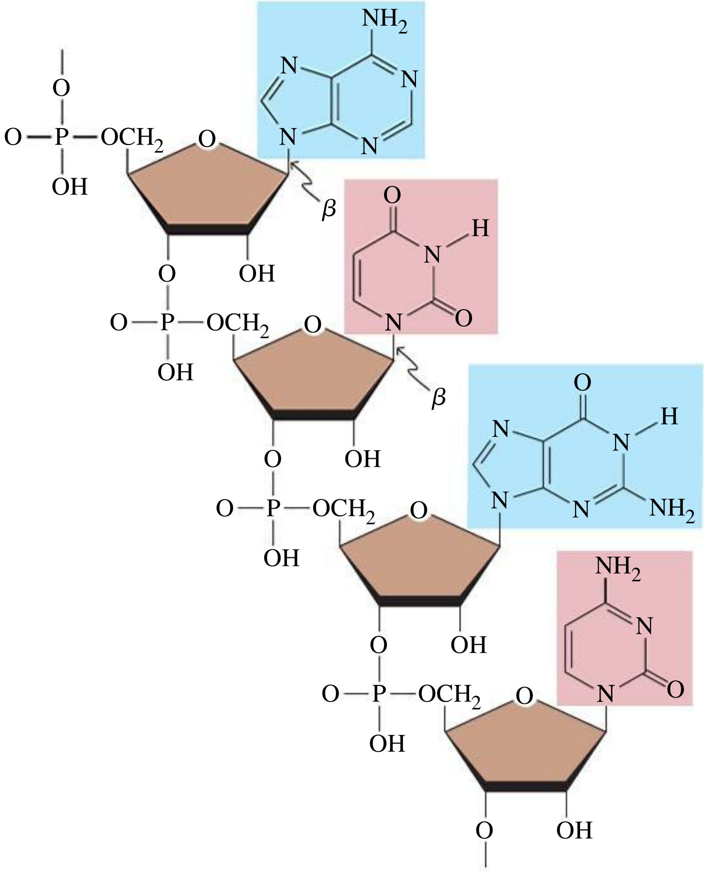


▲ **Hydrogen bonding between a purine and a pyrimidine base.**

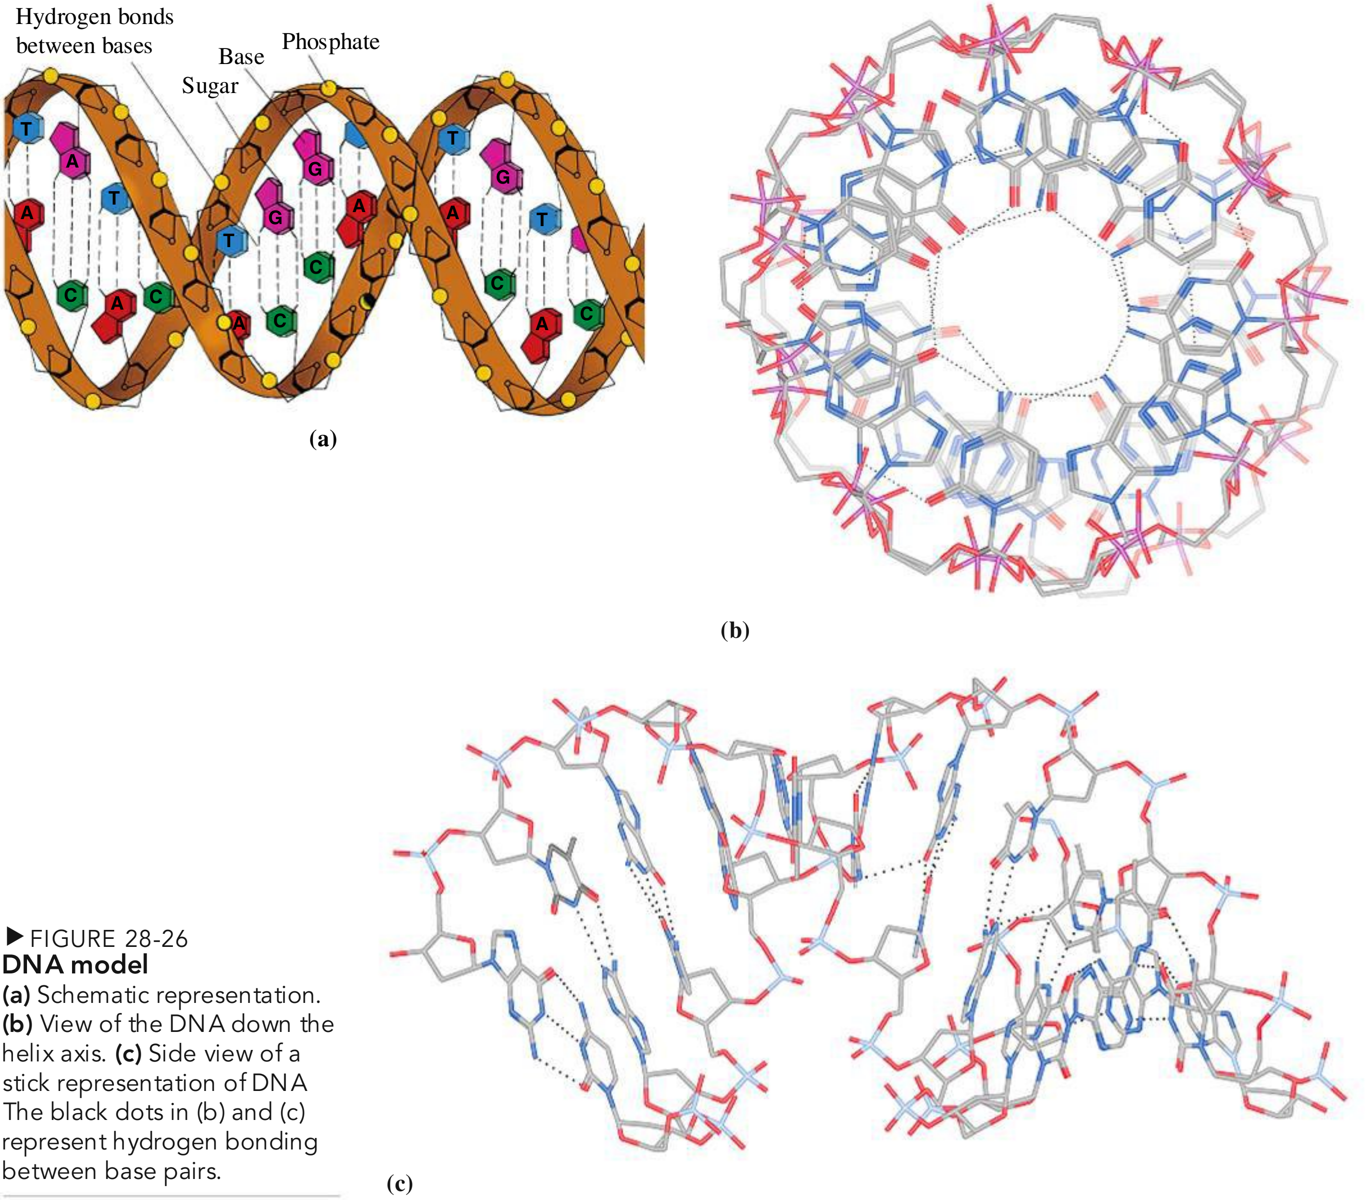
The usual *double helix* form of DNA is shown in Figure 28-26. The postulation of this structure by Francis Crick and James Watson in 1953 was one of the great scientific breakthroughs of modern times. Their work was critically dependent on precise X-ray diffraction studies of DNA done by Maurice Wilkins and Rosalind Franklin and on a set of regularities regarding the purine and pyrimidine bases in nucleic acids discovered by Erwin Chargaff. These regularities, known as the *base-pairing rules*, require the following:

1. The amount of adenine is equal to the amount of thymine $(A = T)$.
2. The amount of guanine is equal to the amount of cytosine $(G = C)$.
3. The total amount of purine bases is equal to the total amount of pyrimidine bases $(G + A = C + T)$.

To maintain the structure of a double helix, hydrogen bonding must occur between the two single strands. The necessary conditions for hydrogen bonding exist only if an A on one strand appears opposite a T on the other, or if a G is



◀ FIGURE 28-25
A portion of a nucleic acid chain

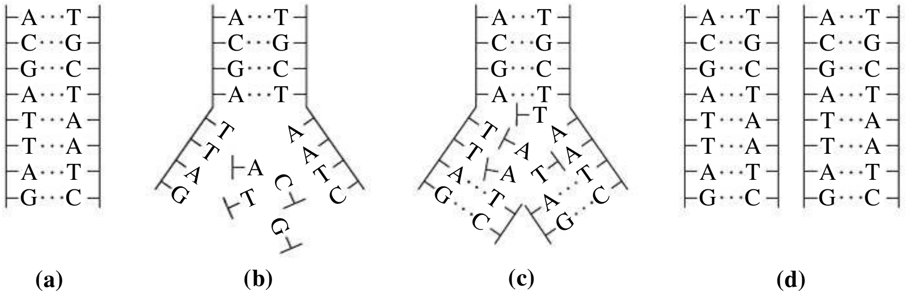


▶ FIGURE 28-26
DNA model
(a) Schematic representation. **(b)** View of the DNA down the helix axis. **(c)** Side view of a stick representation of DNA The black dots in (b) and (c) represent hydrogen bonding between base pairs.

opposite a C. C cannot be paired with T because the relatively small molecules (single ring) would not approach each other closely enough. The combination of G and A cannot occur because the molecules are too large (double rings).

DNA molecules have a unique ability to replicate—that is, to make exact copies of themselves. The critical step in DNA replication requires the molecule to unwind into single strands. As the unwinding occurs, free nucleotides present in the nucleus become attached to the exposed portions of the two single strands, converting each to a new double helix of DNA consisting of one old strand and one new strand (Fig. 28-27).

There are two pieces of evidence, each very convincing, that the process just outlined does indeed occur. First, electron micrographs of the DNA molecule have been obtained that capture DNA in the act of replication. Another elegant experiment involves growing bacteria in a medium containing ^{15}N atoms so that all the N atoms of the bases of the DNA molecules are ^{15}N. The bacteria are then transferred to a nutrient with nucleotides containing normal ^{14}N. Here, the bacteria are allowed to divide and reproduce. The DNA of the offspring cells are then analyzed. Those of the first generation, for example, consist of DNA molecules with one strand having ^{15}N and the other ^{14}N atoms. This is exactly the result to be expected if replication occurs by the unzipping process



▲ FIGURE 28-27
Replication of a DNA molecule
(a) A DNA double helix. **(b)** The two strands begin to unzip. **(c)** Nucleotides from the cellular fluid crowd into the region between the two strands and attach to the exposed strands through hydrogen bonds. **(d)** Two DNA double helices identical to the original one.

described in Figure 28-27. The central importance of the base sequences in DNA is that they act as a chemical template for the formation of an organism's proteins; that is, they act as genes. This, together with a discussion of RNA, is outlined in Focus On 28 on the Mastering Chemistry website.

MasteringCHEMISTRY **www.masteringchemistry.com**

How is the genetic code contained within DNA transmitted to the sites of protein synthesis? The process involves molecules acting as initiators, messengers, movers, and terminators. For a discussion of the process and the roles that various molecules play in it, go to the Focus On feature for Chapter 28, Protein Synthesis and the Genetic Code, on the MasteringChemistry site.

Summary

28-1 Chemical Structure of Living Matter: An Overview—Four general categories of substances found in living organisms are lipids, carbohydrates, proteins, and nucleic acids. **Cells**, which are the fundamental structural units of living things, contain macromolecules from each of these categories (Fig. 28-2).

28-2 Lipids—A range of substances of biological origin that are soluble in nonpolar or low-polarity solvents are classified as **lipids**. One familiar group of lipids is the **triglycerides**, esters of glycerol with long-chain monocarboxylic (fatty) acids. If saturated fatty acids predominate, the triglyceride is a **fat**. If unsaturation (in the form of double bonds) occurs in some of the fatty acid components, the triglyceride is an **oil**. **Saponification**, the hydrolysis of a triglyceride with a strong base, yields glycerol and salts of the fatty acid components (equation 28.1). The salt of a fatty acid is called a **soap**.

28-3 Carbohydrates—The most common among simple **carbohydrate** molecules are five- and six-carbon-chain polyhydroxy aldehydes and ketones. These molecules can be represented by **Fischer projection formulas**, which project the three-dimensional structures in two dimensions (Fig. 28-5). Carbohydrates contain chiral carbon atoms, existing therefore as optical isomers. One isomer, designated *d* or $(+)$, rotates the plane of polarized light "to the right" (clockwise) and is said to be **dextrorotatory**. Its enantiomer, designated *l* or $(-)$, rotates polarized light "to the left" (counterclockwise) and is **levorotatory** (Fig. 28-4). Commonly encountered for carbohydrates with more than one chiral center are **diastereomers**, optical isomers that are not mirror images and hence not enantiomers. The arrangement of groups at an asymmetric carbon atom is called the **absolute configuration** and is designated by the *R*, *S* system of nomenclature. Syntheses of carbohydrates generally lead to equal amounts of enantiomers in mixtures referred to as **racemic mixtures**.

Monosaccharides are the simplest carbohydrate structures (Fig. 28-7). Two to ten monosaccharide units can join to form an **oligosaccharide**, for example, two monosaccharide units join to form a disaccharide (Fig. 28-8). Together, monosaccharides and oligosaccharides are also known as **sugars**. **Polysaccharides** contain from a few to a few thousand monosaccharide units. The most common of these are starch, glycogen, and cellulose (Fig. 28-9). A **reducing sugar** is one that can reduce Cu^{2+} to copper(I) oxide.

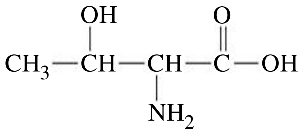
28-4 Proteins—Some 20 different **α-amino acids** (Table 28.3) are the basic building blocks of **proteins**, which consist of a long chain of amino acids. An α-amino acid has an amino group and a carboxyl group connected to the rest of the molecule at the α carbon atom. The pH at which the amino acid exists predominantly as a dipolar ion, a **zwitterion**, is the **isoelectric point**. Two amino acid molecules may join by eliminating a H_2O molecule between them to form a **peptide bond** (equation 28.5). When several peptides are linked together, the chain is referred to as a **polypeptide** chain. The linear sequence of amino acids of a protein is known as its **primary structure** (Fig. 28-11). The structure or shape of the entire amino acid chain in a protein is referred to as its **secondary structure**. Types of secondary structure include helical coils (Fig. 28-12) and pleated sheets (Fig. 28-13). **Tertiary structure** is the three-dimensional arrangement of the amino acid chains with respect to each other (Fig. 28-14), while **quaternary structure** is the arrangement of different polypeptide chains to form a larger biomolecule, such as hemoglobin (Fig. 28-16). **Denaturation** occurs when a protein loses it biological activity due to the unfolding of its tertiary structure.

28-5 Aspects of Metabolism—Lipids, carbohydrates, and proteins are complex molecules that are broken down into their simplest units as part of the process of **metabolism** (Fig. 28-17). Carbohydrates are degraded into monosaccharides, proteins into amino acids, and lipids into glycerol and fatty acids. Ultimately, these degradation products are decomposed into still smaller molecules, such as CO_2, H_2O, NH_3, and urea. **Enzymes** are proteins that catalyze metabolic reactions. Energy released in catabolic processes is used to convert **adenosine diphosphate (ADP)** to **adenosine triphosphate (ATP)**, which can then supply the energy needs of other processes.

28-6 Nucleic Acids—**Nucleic acids** are made up of pentose sugars, purine and pyrimidine bases, and phosphate groups (Fig. 28-24). Two classes of nucleic acids are **ribonucleic acid (RNA)** and **deoxyribonucleic acid (DNA)** (Figs. 28-25 and 28-26). RNA contains the sugar ribose, while DNA contains the sugar 2-deoxyribose. Nucleic acids carry the information that directs the metabolic activity of cells and the hereditary information that is passed from one generation to the next.

Integrative Example

L-Threonine is one of the essential amino acids. It is found in animal protein (for example, eggs and milk) but is missing in some grains, such as rice. It is now common practice to fortify grains with the essential amino acids that they lack. The structure of L-threonine is shown below.



$$\mathrm{CH_3{-}\overset{OH}{\overset{|}{C}H}{-}\underset{\underset{NH_2}{|}}{CH}{-}\overset{O}{\overset{\|}{C}}{-}OH}$$

$$pK_{a_1} = 2.15 \quad pK_{a_2} = 9.12$$

Use the above data to determine the principal form of L-threonine and the direction that it will migrate under the influence of an electric field in a gel that is 0.25 M NaH_2PO_4 and 0.50 M Na_2HPO_4.

Analyze

The key to this problem is to recognize that the NaH_2PO_4/Na_2HPO_4 mixture is a buffer that controls the pH of the gel. Once the pH of the gel is established we can identify the ionization state for the bulk of the L-threonine and hence the direction it will migrate.

Solve

Use pK_{a_2} from Table 16.4 and the Henderson–Hasselbalch equation to calculate the pH of the gel.

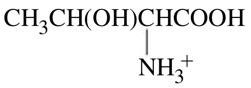
$$\mathrm{pH} = pK_{a_2} + \log([HPO_4{}^{2-}]/[H_2PO_4{}^{-}])$$

and

$$\mathrm{pH} = 7.20 + \log(0.50/0.25) = 7.50$$

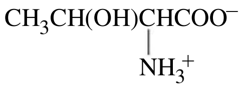
The structures of the three ionic forms in which L-threonine can appear are

Acidic solution:



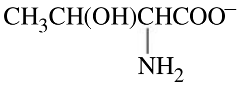
$$\mathrm{CH_3CH(OH)\underset{\underset{NH_3^+}{|}}{C}HCOOH}$$

Isoelectric point:



$$\mathrm{CH_3CH(OH)\underset{\underset{NH_3^+}{|}}{C}HCOO^-}$$

Basic solution:



$$\mathrm{CH_3CH(OH)\underset{\underset{NH_2}{|}}{C}HCOO^-}$$

The pH at the first equivalence point in the titration of a weak diprotic acid is given by equation (17.5). Applied to L-threonine, the result is

$$\mathrm{pH} = \frac{pK_{a_1} + pK_{a_2}}{2} = \frac{2.15 + 9.12}{2} = 5.64$$

The predominant species at this first equivalence point of pH $= 5.64$ is the dipolar zwitterion, which would not migrate at all in an electric field. However, in the gel medium of pH $= 7.50$ the hydroxide ion concentration is 100 times as great. The predominant species is the anion with charge -1. This form of the L-threonine migrates toward the positive electrode, the anode.

Assess

This problem suggests two ways to establish the isoelectric point of an amino acid. The first, used here, is to calculate pI by combining pK_a values of a polyprotic amino acid. Another way is to find the pH of a gel medium in which the amino acid does not migrate in the presence of an applied electric field, hence pH $=$ pI. Additionally, migration through an electric field in a gel (gel electrophoresis) can be used to separate amino acid mixtures.

PRACTICE EXAMPLE A: Osmotic pressure experiments are one method to determine the molar mass of proteins. Myoglobin from beef heart muscle has a molar mass of 16.9 kg per mole. If you dissolve 0.500 g of beef heart myoglobin in 25.0 mL of water at $T = 298$ K, what is the height, h, of the solution generated in an osmotic pressure experiment? [*Hint*: The osmotic pressure is equivalent to the hydrostatic pressure given in equation (6.2).]

PRACTICE EXAMPLE B: Carbonic anhydrase is a metalloenzyme that reversibly catalyzes the reaction of carbon dioxide to bicarbonate ion:

$$CO_2(aq) + H_2O(l) \rightleftharpoons HCO_3^-(aq) + H^+(aq)$$

This is one mechanism of moving carbon dioxide from the cell to the lungs in which the bicarbonate ion is converted to carbon dioxide and then exhaled. **(a)** Draw a possible mechanism for the hydration of carbon dioxide to bicarbonate ion in which you illustrate the movement of electrons. **(b)** In Chapter 14, equation (14.36) represents the rate of catalysis versus substrate concentration. Equation (14.36) can be transformed to a linear form known as the Lineweaver-Burk equation:

$$\frac{1}{V} = \frac{1}{V_{\max}} + \frac{K_M}{V_{\max}} \times \frac{1}{[S]}$$

where $V_{\max} = k_2[E]_0$. Determine K_M and k_2, given the following data taken at 0.5 °C with an initial enzyme concentration of 2.3 nM.

Rate[a], M s^{-1}	[CO$_2$], mM
9.02×10^{-5}	1.25
1.67×10^{-4}	2.5
2.90×10^{-4}	5.0
6.47×10^{-4}	20.0

[a] Data from H. DeVoe and G. B. Kistiakowsky, *J. Amer. Chem. Soc.*, **83**, 274 (1961).

Exercises

Structure and Composition of the Cell

Exercises 1 to 4 refer to a typical Escherichia coli *bacterium. This is a cylindrical cell about 2 μm long and 1 μm in diameter, weighing about 2×10^{-12} g and containing about 80% water by volume.*

1. The intracellular pH is 6.4 and $[K^+] = 1.5 \times 10^{-4}$ M. Determine the number of **(a)** H_3O^+ ions and **(b)** K^+ ions in a typical cell.

2. Calculate the number of lipid molecules present, assuming their average molecular mass to be 700 u and the lipid content to be 2% by mass.

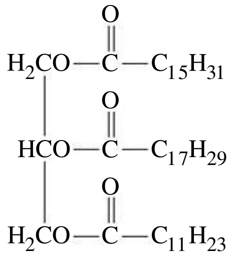
3. The cell is about 15% protein by mass with 90% of the protein in the cytoplasm. Assuming an average molecular mass of 3×10^4 u, how many protein molecules are present in the cytoplasm?

4. A single chromosomal DNA molecule contains about 4.5 million nucleotide units. If this molecule were extended so that the nucleotide units were 450 pm apart, what would be the length of the molecule? How does this compare with the length of the cell itself? What does this result suggest about the shape of the DNA molecule?

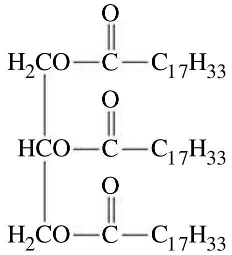
Lipids

5. Name the following compounds.

(a)



(b)



(c) $C_{13}H_{27}CO_2^-Na^+$

6. Write structural formulas for the following.
   - **(a)** glyceryl palmitolauroeleostearate
   - **(b)** tripalmitin
   - **(c)** potassium myristate
   - **(d)** butyl oleate

7. Describe the similarities and differences between **(a)** trilaurin and trilinolein, **(b)** a soap and a phospholipid such as a lecithin.

8. Write a structural formula for a generic phosphatidic acid—an acid that produces a cephalin when esterified with ethanolamine and a lecithin when esterified with choline. Mono- and diglycerides are found in many processed foods. Write structural formulas for a generic monoglyceride and a generic diglyceride.

9. Oleic acid is a moderately unsaturated fatty acid. Linoleic acid is *polyunsaturated*. What structural feature characterizes polyunsaturated fatty acids? Is stearic acid polyunsaturated? Is eleostearic acid? Why do you suppose safflower oil is so highly recommended in dietary programs?

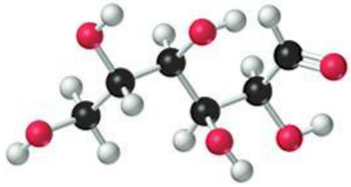
10. Corn oil and safflower oil are popular cooking oils (Table 28.2). They can be converted to solid fats by hydrogenation. Which would consume the greater amount of $H_2(g)$ in its hydrogenation to a solid fat, 1 kg of corn oil or 1 kg of safflower oil? Explain.

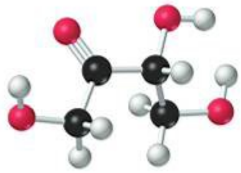
11. Write structural formulas to represent the products of the saponification of tripalmitin with NaOH(aq).

12. Calculate the maximum mass of the sodium soap that can be prepared from 105 g of glyceryl trimyristate.

Carbohydrates

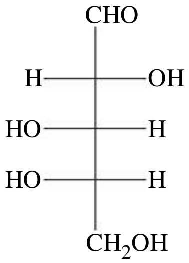
13. Characterize the two sugars represented below using the terminology from page 1273. Further indicate whether the sugar has a D or L configuration.





14. Write the structure for the straight-chain form of L-glucose. Does the structure determine if this isomer is levorotatory? Explain.

15. From the given structure of L-(+)-arabinose below, derive the structure of **(a)** D-(−)-arabinose; **(b)** a diastereomer of L-(+)-arabinose.



L-(+)-Arabinose

16. Describe the similarities and differences in the structures of the following three compounds. (a) β-D-(+)-glucose; **(b)** D-(−)-arabinose; **(c)** D-(+)-glucose.

17. The following terms are all related to stereoisomers and their optical activity. Explain the meaning of each: **(a)** dextrorotatory; **(b)** levorotatory; **(c)** racemic mixture; **(d)** (*R*).

18. The following terms are all related to optical isomers. Explain the meaning of each: **(a)** diastereomers; **(b)** enantiomers; **(c)** (−); **(d)** D configuration.

19. Explain the meaning of the term *reducing sugar*. What structural feature characterizes a reducing sugar, and what is the test for a reducing sugar? What mass of $Cu_2O(s)$ should be produced when 0.500 g glucose is subjected to this test?

20. There are eight aldopentoses. Draw their structures, and indicate which are enantiomers.

21. The pure α and β forms of D-glucose rotate the plane of polarized light to the right by 112° and 18.7°, respectively (denoted as +112 and +18.7). Are these two forms of glucose enantiomers or diastereomers?

22. When a mixture of the pure α and β forms of D-glucose is allowed to reach equilibrium in solution, the rotation changes to +52.7 (a phenomenon known as mutarotation). What are the percentages of the α and β forms in the equilibrium mixture? [*Hint:* Refer to Exercise 21.]

Fischer Projections and *R*, *S* Nomenclature

23. For each pair of Fischer projections below, decide whether they represent the same compound, enantiomers, or diastereomers. Check your conclusion by designating the configuration at each stereocenter as *R* or *S*.

Amino Acids, Polypeptides, and Proteins

27. Describe what is meant by each of the following terms, using specific examples where appropriate: **(a)** α-amino acid; **(b)** zwitterion; **(c)** isoelectric point; **(d)** peptide bond; **(e)** tertiary structure.

28. Describe what is meant by each of the following terms, using specific examples where appropriate: **(a)** polypeptide; **(b)** protein; **(c)** N-terminal amino acid; **(d)** α helix; **(e)** denaturation.

29. Write the formulas of the species expected if the amino acid phenylalanine is maintained in **(a)** 1.0 M HCl; **(b)** 1.0 M NaOH; **(c)** a buffer solution with pH = 5.7.

30. Draw plausible structures for the amino acid histidine at **(a)** pH = 3.0; **(b)** pH = 7.6; **(c)** pH = 12.0.

31. Write the structures of **(a)** alanylcysteine; **(b)** threonylvalylglycine.

32. For the polypeptide Met-Val-Thr-Cys, **(a)** write the structural formula; **(b)** name the polypeptide. [*Hint:* Which is the N-terminal, and which is the C-terminal amino acid?]

33. A mixture of the amino acids lysine, proline, and aspartic acid is placed in a gel buffered at pH 6.3. An electric current is applied between an anode and a cathode immersed in the gel. Toward which electrode will each amino acid migrate?

34. A mixture of the amino acids histidine, glutamic acid, and phenylalanine is placed in a gel buffered at pH 5.7. An electric current is applied between an anode and a cathode immersed in the gel. Toward which electrode will each amino acid migrate?

35. Draw condensed structural formulas showing what form you would expect for the essential amino acid threonine **(a)** in strongly acidic solutions; **(b)** at the isoelectric point; and **(c)** in strongly basic solutions.

36. Draw condensed structural formulas for the following amino acids buffered at pH 6.0: **(a)** aspartic acid; **(b)** lysine; and **(c)** alanine.

37. Write the structures of **(a)** the different tripeptides that can be obtained from a combination of alanine, serine, and lysine; **(b)** the tetrapeptides containing two serine and two alanine amino acid units.

38. Write the structures of the different tetrapeptides that can be obtained from a combination of alanine, lysine, serine, and phenylalanine. Give the abbreviated formula of each (such as Ala-Lys-Ser-Phe), starting at the N-terminal end.

39. After undergoing complete hydrolysis, a polypeptide yields the following amino acids: Gly, Leu, Ala, Val, Ser, Thr. Partial hydrolysis yields the following fragments: Ser-Gly-Val, Thr-Val, Ala-Ser, Leu-Thr-Val, Gly-Val-Thr. An experiment using a marker establishes that Ala is the N-terminal amino acid.

(a) Establish the amino acid sequence in this polypeptide.

(b) What is the name of the polypeptide?

40. After undergoing complete hydrolysis, a polypeptide yields the following amino acids: Ala, Gly, Lys, Ser, Phe. Partial hydrolysis yields the following fragments: Ala-Lys-Ser, Gly-Phe-Gly, Ser-Gly, Gly-Phe, Lys-Ser-Gly. An experiment using a marker establishes that Ala is the N-terminal amino acid.

(a) Establish the amino acid sequence in this polypeptide.

(b) What is the name of the polypeptide?

41. Describe what is meant by the primary, secondary, and tertiary structure of a protein. What is the quaternary structure? Do all proteins have a quaternary structure? Explain.

42. Sickle-cell anemia is sometimes referred to as a "molecular" disease. Comment on the appropriateness of this term.

43. The amino acid (*R*)-alanine is found in insect larvae. Draw the Fischer projection of this amino acid.

44. The amino acid (*R*)-serine is found in earthworms. Draw the Fischer projection of this amino acid.

45. Draw the dashed-wedged line structure for (*S*)-alanine and (*S*)-phenylalanine.

46. Draw the dashed-wedged line structure for (*R*)-proline and (*S*)-valine.

Nucleic Acids

47. What are the two major types of nucleic acids? List their principal components.

48. DNA has been called the "thread of life." Comment on the appropriateness of this expression.

49. If one strand of a DNA molecule has the base sequence of AGC, what must be the sequence on the opposite strand? Draw a structure of this portion of the double helix, showing all hydrogen bonds.

50. If one strand of a DNA molecule has the base sequence TCT, what must be the sequence on the opposite strand? Draw a structure of this portion of the double helix, showing all hydrogen bonds.

Integrative and Advanced Exercises

51. The protein molecule hemoglobin contains four iron atoms. The mass percent iron in hemoglobin is 0.34%. What is the molecular mass of hemoglobin?

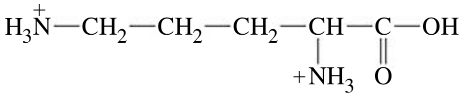
52. A 1.00 mL solution containing 1.00 mg of an enzyme was deactivated by the addition of 0.346 μmol $AgNO_3$. What is the *minimum* molecular mass of the enzyme? Why does this calculation yield only a minimum value?

53. What minimum volume of natural gas is needed to produce the hydrogen consumed in converting 15.5 kg of the oil glyceryl trioleate (triolein) to the fat glyceryl tristearate (tristearin)? The natural gas is 92.0% CH_4 and 8.0% C_2H_6 by volume and is measured at 25.5 °C and 756 mmHg pressure. The hydrogen is produced by steam re-forming the natural gas. Assume that natural gas and steam are the only reactants and that carbon monoxide is the only product other than hydrogen.

54. The text states that there are 16 possible aldohexoses. Draw their structures, and indicate which are enantiomers.

55. The term "epimer" is used to describe diastereomers that differ in the configuration about a *single* carbon atom. Which pairs of the eight possible aldopentoses are epimers?

56. The amino acid ornithine, not normally found in proteins, has the following structure at a pH of 1.0.



$$H_3\overset{+}{N}-CH_2-CH_2-CH_2-\underset{+NH_3}{\underset{|}{CH}}-\underset{O}{\underset{\|}{C}}-OH$$

$$pK_{a_1} = 1.94; \quad pK_{a_2} = 8.65; \quad pK_{a_3} = 10.76$$

What is the p*I* value of this amino acid?

57. In the experiment described on page 1294, the first-generation offspring of DNA molecules each contained one strand with ^{15}N atoms and one with ^{14}N. If the experiment were carried through a second, third, and fourth generation, what fractions of the DNA molecules would still have strands with ^{15}N atoms?

58. Bradykinin is a nonapeptide obtained by the partial hydrolysis of blood serum protein. It causes a lowering of blood pressure and an increase in capillary permeability. Complete hydrolysis of bradykinin yields three proline (Pro), two arginine (Arg), two phenylalanine (Phe), one glycine (Gly), and one serine (Ser) amino acid units. The N-terminal and C-terminal units are both arginine (Arg). In a hypothetical experiment, partial hydrolysis and sequence proof reveals the following fragments: Gly-Phe-Ser-Pro; Pro-Phe-Arg; Ser-Pro-Phe; Pro-Pro-Gly; Pro-Gly-Phe; Arg-Pro-Pro; Phe-Arg. Deduce the sequence of amino acid units in bradykinin.

59. With the aid of the table in Focus On 28 on the Mastering Chemistry website, propose a plausible sequence on a DNA strand that would code for the synthesis of the polypeptide Ser-Gly-Val-Ala. Why is there more than one possible sequence for the DNA strand?

60. Refer to the Integrative Example. A 1.00 g sample of threonine is dissolved in 10.0 mL of 1.00 M HCl, and the solution is titrated with 1.00 M NaOH. Sketch a titration curve for the titration, indicating the approximate pH at representative points on the curve [such as the initial pH, the half-neutralization point(s) and the equivalence point(s)].

61. Projection formulas impose certain limitations and care must be taken in drawing and manipulating them. Use (*R*)-(+)-glyceraldehyde as an example and show that:
(a) Rotating the Fischer projection by 90° in the plane of the paper produces the opposite absolute configuration. What is the effect of rotation by 180° and 270° in the plane of the paper?
(b) Interchanging two substituents converts one enantiomer into the other. What is the effect of two such interchanges?

62. A pentapeptide was isolated from a cell extract and purified. A portion of the compound was treated with 2,4-dinitrofluorobenzene (DNFB), and the resulting material hydrolyzed (recall Figure 28-10). Analysis of the hydrolysis products revealed one mole of DNP-methionine, two moles of methionine, and one mole each of serine and glycine. A second portion of the original compound was partially hydrolyzed and separated into four products. Separately, the four products were hydrolyzed further, giving the following four sets of compounds: **(1)** one mole of DNP-methionine, one mole of methionine, and one mole of glycine; **(2)** one mole of DNP-methionine and one mole of methionine; **(3)** one mole of DNP-serine and one mole of methionine; **(4)** one mole of DNP-methionine, one mole of methionine, and one mole of serine. What is the amino acid sequence of the pentapeptide?

63. Eighteen of the nineteen 1-amino acids have the *S* configuration at the α carbon (the first carbon after the carboxyl carbon). Cysteine is the only 1-amino acid that has an *R* configuration. Explain.

64. The systematic (IUPAC) name for the amino acid threonine is (2*S*,3*R*)-2-amino-3-hydroxybutanoic acid. The systematic name indicates that threonine has two stereocenters, at positions 2 and 3, with *S* and *R* configurations, respectively. Draw the Fischer projection of threonine. How many other possible stereoisomers of threonine are there?

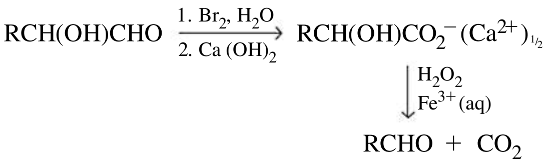
65. Coupling ATP hydrolysis to a thermodynamically unfavorable reaction can shift the equilibrium of a reaction (see Chapter 19).
(a) Calculate *K* for the hypothetical reaction $A \longrightarrow B$ when $\Delta G°'$ is 23 kJ mol^{-1} at 25 °C.
(b) Calculate *K* for the same reaction when it is coupled to the hydrolysis of ATP ($\Delta G°' = -30$ kJ mol^{-1}). Compare with the value obtained in part (a).
(c) Many cells maintain [ATP] to [ADP] ratios of 400 or more. Calculate the ratio of [B] to [A] when [ATP]/[ADP] = 400 and $P_i] = 5$ mM. Compare this ratio to that for the uncoupled reaction.

Feature Problems

66. Useful information about the structures of triglycerides can be obtained through saponification reactions. *The saponification value of a triglyceride is the number of milligrams of KOH required to saponify 1.00 g of the triglyceride.* Unsaturation in the fatty acids in triglycerides can be discovered by studying reactions in which I_2 is added across double bonds. *The iodine number is the number of grams of I_2 that reacts with 100 g of a triglyceride.*
(a) Determine the saponification value of glyceryl tristearate and the iodine number of glyceryl trioleate.
(b) Castor oil is a mixture of triglycerides with about 90% of its fatty acid content in ricinoleic acid, $CH_3(CH_2)_5CH(OH)CH{=}CH(CH_2)_7COOH$. Estimate the saponification value and the iodine number of castor oil.

(c) Based on the composition given in Table 28.2, estimate the range of values for the saponification value and iodine number of safflower oil.

67. The so-called Ruff degradation is a chain-shortening reaction in which an aldose chain is shortened by one C atom, hexoses, for example, being converted into pentoses. In the Ruff degradation, the calcium salt of an aldonic acid (the corresponding carboxylic acid of an aldose) is oxidized with hydrogen peroxide. Ferric ion catalyzes the reaction. The calcium salt of the aldonic acid necessary for the Ruff degradation is obtained by oxidizing an aldose with an aqueous solution of bromine and then adding calcium hydroxide. The reaction scheme is as follows



$$\mathrm{RCH(OH)CHO} \xrightarrow[\text{2. Ca (OH)}_2]{\text{1. Br}_2\text{, H}_2\text{O}} \mathrm{RCH(OH)CO_2^-(Ca^{2+})_{1/2}}$$

$$\Big\downarrow \; \mathrm{H_2O_2},\ \mathrm{Fe^{3+}(aq)}$$

$$\mathrm{RCHO + CO_2}$$

where R represents the rest of the chain of the aldose.

(a) Show that D-glucose can be degraded into D-arabinose. Which other aldose can be degraded into D-arabinose?

(b) Which two monosaccharides can be degraded into D-glyceraldehyde by employing the Ruff degradation only once?

68. If D-(+)-glyceraldehyde is treated with HCN in aqueous solution under basic conditions for three days at room temperature, cyanohydrins are formed (see Chapter 27). The cyanohydrins are not isolated, but are hydrolyzed to hydroxyacids in the same reaction mixture using dilute sulfuric acid. In this process, a new stereocenter is formed in the molecule. The products are diastereomers, formed in unequal amounts, and separable from each other by recrystallization because of their different physical properties, including solubilities. The trihydroxybutanoic acids are separated and then oxidized to tartaric acid with dilute nitric acid, which oxidizes only the primary alcohol group.

(a) Ignoring stereochemistry, draw the reaction sequence for the transformations described above and hence deduce the structure of tartaric acid.

(b) Starting from the Fischer projection of D-(+)-glyceraldehyde and using the reaction scheme from part (a), draw Fischer projections of the two trihydroxybutanoic acids formed and designate the chiral centers as *R* or *S*.

(c) Starting from the Fischer projection of D-(+)-glyceraldehyde and using the reaction scheme from part (a), draw Fischer projections of the two forms of tartaric acid formed and designate the chiral centers as *R* or *S*.

(d) One form of tartaric acid obtained is optically active, rotating the plane of polarized light in a negative sense (−). The other isomer formed, called *meso*-tartaric acid, is not optically active. Explain why the other isomer is not optically active. Draw the dashed-wedged line structure that corresponds to the Fischer projection of *meso*-tartaric acid. Can you describe how the two halves of the molecule are related? Using Fischer projections, write equations for the conversion of L-(−)-glyceraldehyde to tartaric acid. Show clearly the stereochemistry of the tartaric acids that are formed, and indicate whether you expect them to be optically active.

Self-Assessment Exercises

69. In your own words, define the following terms or symbols: **(a)** (+); **(b)** L; **(c)** sugar; **(d)** α-amino acid; **(e)** isoelectric point.

70. Briefly describe each of the following ideas, phenomena, or methods: **(a)** saponification; **(b)** chiral carbon atom; **(c)** racemic mixture; **(d)** denaturation of a protein.

71. Explain the important distinctions between each pair of terms: **(a)** fat and oil; **(b)** enantiomer and diastereomer; **(c)** primary and secondary structure of a protein; **(d)** DNA and RNA; **(e)** ADP and ATP.

72. The substance *glyceryl trilinoleate* (linoleic acid: $C_{17}H_{31}COOH$) is best described as a **(a)** fat; **(b)** oil; **(c)** wax; **(d)** fatty acid; **(e)** phospholipid.

73. The best description of the observed rotation of plane polarized light by a sugar sample labeled DL-erythrose is **(a)** to the left; **(b)** to the right; **(c)** alternately to the right and then to the left; **(d)** neither to the left nor the right; **(e)** clockwise.

74. Of the following names, the one that refers to a simple sugar in its cyclic (ring) form is **(a)** β-galactose; **(b)** L-(−)-glyceraldehyde; **(c)** D-(+)-glucose; **(d)** DL-erythrose; **(e)** (*R*)-(+)-glyceraldehyde.

75. The coagulation of egg whites by boiling is an example of **(a)** saponification; **(b)** inversion of a sugar; **(c)** hydrolysis of a protein; **(d)** denaturation of a protein; **(e)** condensation of amino acids.

76. A molecule in which the energy of metabolism is stored is **(a)** glucose; **(b)** DNA; **(c)** RNA; **(d)** glycerol; **(e)** ATP.

77. Of the following, the one that is not a constituent of a nucleic acid chain is **(a)** purine base; **(b)** phosphate group; **(c)** glycerol; **(d)** pentose sugar; **(e)** pyrimidine base.

78. The structure of the DNA molecule is best described as **(a)** a random coil; **(b)** a double helix; **(c)** a pleated sheet; **(d)** partly coiled; **(e)** a branched chain.

79. What is the maximum mass of a sodium soap that can be prepared from 125 g of glyceryl tripalmitate?

80. With reference to Figure 28-25, identify the purine bases, the pyrimidine bases, the pentose sugars, and the phosphate groups. Is this a chain of DNA or RNA? Explain.

81. The *R* group $-CH_2CH_2NH_2$ is that of what amino acid? **(a)** alanine; **(b)** serine; **(c)** threonine; **(d)** arginine; **(e)** none of these.

82. Which molecule is not optically active?
(a) 1,2-dichlorobutane; **(b)** 1,4-dichlorobutane;
(c) 1,3-dichlorobutane; **(d)** 1,2-dichloropropane;
(e) none of these.

83. Which of the following amino acids does not have a chiral carbon? **(a)** glycine; **(b)** alanine; **(c)** threonine; **(d)** lysine; **(e)** none of these.

84. Enantiomers always **(a)** have an asymmetric carbon; **(b)** have different physical properties; **(c)** change the color of light; **(d)** rotate polarized light; **(e)** none of these.

85. The *R* group of valine is **(a)** $—CH_2OH$; **(b)** $—CH_2COOH$; **(c)** $—CH(CH_3)_2$; **(d)** $—CH_2CH_2CH_2CH_2NH_2$; **(e)** none of these.

86. Amino acids are joined into proteins by **(a)** 3′—5′ linkage; **(b)** a glycosidic bond; **(c)** $\beta(1 \longrightarrow 4)$ linkage; **(d)** a condensation reaction; **(e)** none of these.

87. Which of the following fatty acids is unsaturated? **(a)** palmitic acid; **(b)** oleic acid; **(c)** lauric acid; **(d)** stearic acid; **(e)** none of these.

88. Upon complete hydrolysis of a pentapeptide, the following amino acids are obtained: valine, phenylalanine, glycine, cysteine, and tyrosine. Partial hydrolysis yields the following fragments: Val-Phe; Cys-Gly; Cys-Val-Phe; Tyr-Phe. If glycine is the N-terminal acid, what is the sequence of amino acids in the polypeptide?

89. Appendix E describes a useful study aid known as concept mapping. Using the method presented in Appendix E, construct a concept map illustrating the concepts in Section 28-4.

A

Appendix

Mathematical Operations

A-1 Exponential Arithmetic

Measured quantities in this text range from very small to very large. For example, the mass of an individual hydrogen atom is 0.00000000000000000000000167 g, and the number of molecules in 18.0153 g of the substance water is 602,214,000,000,000,000,000,000. These numbers are difficult to write in conventional form and are even more cumbersome to handle in numerical calculations. We can greatly simplify them by expressing them in exponential form. The *exponential form* of a number consists of a coefficient (a number with value between 1 and 10) multiplied by a power of 10.

The number 10^n is the *nth power* of 10. If n is a *positive* quantity, 10^n is *greater than 1*. If n is a *negative* quantity, 10^n is *between 0 and 1*. The value of $10^0 = 1$.

Positive powers	*Negative powers*
$10^0 = 1$	$10^0 = 1$
$10^1 = 10$	$10^{-1} = \frac{1}{10} = 0.1$
$10^2 = 10 \times 10 = 100$	$10^{-2} = \frac{1}{10 \times 10} = \frac{1}{10^2} = 0.01$
$10^3 = 10 \times 10 \times 10 = 1000$	$10^{-3} = \frac{1}{10 \times 10 \times 10} = \frac{1}{10^3} = 0.001$

To express the number 3170 in exponential form, we write

$$3170 = 3.17 \times 1000 = 3.17 \times 10^3$$

For the number 0.00046 we write

$$0.00046 = 4.6 \times 0.0001 = 4.6 \times 10^{-4}$$

A simpler method of converting a number to exponential form that avoids intermediate steps is illustrated below.

$$3\,\underbrace{1\,7\,0}_{3\;2\;1} = 3.17 \times 10^3$$

$$0.\underbrace{0\,0\,0\,4}_{1\;2\;3\;4}\,6 = 4.6 \times 10^{-4}$$

That is, to convert a number to exponential form,

- Move the decimal point to obtain a coefficient with value between 1 and 10.
- The exponent (power) of 10 is equal to the number of places the decimal point is moved.
- If the decimal point is moved *to the left*, the exponent of 10 is *positive*.
- If the decimal point is moved *to the right*, the exponent of 10 is *negative*.

To convert a number from exponential form to conventional form, move the decimal point the number of places indicated by the power of 10. That is,

$$6.1 \times 10^{6} = 6.\underbrace{1\,0\,0\,0\,0\,0}_{1\ 2\ 3\ 4\ 5\ 6} = 6{,}100{,}000$$

$$8.2 \times 10^{-5} = 0.\underbrace{0\,0\,0\,0\,8}_{5\ 4\ 3\ 2\ 1}.2 = 0.000082$$

▶ The instructions given here are for a typical electronic calculator. The keystrokes required with your calculator may be somewhat different. Look for specific instructions in the instruction manual supplied with the calculator.

Electronic calculators designed for scientific and engineering work easily accommodate exponential numbers. A typical procedure is to key in the number, followed by the key "EXP" or "EE." Thus, the keystrokes required for the number 6.57 × 10^3 are

$$\boxed{6}\,\boxed{.}\,\boxed{5}\,\boxed{7}\,\boxed{\text{EXP}}\,\boxed{3}$$

and the result displayed is $\boxed{6.57^{03}}$

For the number 6.25 × 10^{-4}, the keystrokes are

$$\boxed{6}\,\boxed{.}\,\boxed{2}\,\boxed{5}\,\boxed{\text{EXP}}\,\boxed{4}\,\boxed{\pm}$$

and the result displayed is $\boxed{6.25^{-04}}$

Some calculators have a mode setting that automatically converts all numbers and calculated results to the exponential form, regardless of the form in which numbers are entered. In this mode setting you can generally also set the number of significant figures to be carried in displayed results.

Addition and Subtraction

To add or subtract numbers written in exponential form, first express each quantity as *the same power of 10*. Then add and/or subtract the coefficients as indicated. That is, treat the power of 10 as you would a unit common to the terms being added and/or subtracted. In the example that follows, convert 3.8 × 10^{-3} to 0.38 × 10^{-2} and use 10^{-2} as the common power of 10.

$$\begin{aligned}(5.60 \times 10^{-2}) + (3.8 \times 10^{-3}) - (1.52 \times 10^{-2}) &= (5.60 + 0.38 - 1.52) \times 10^{-2} \\ &= 4.46 \times 10^{-2}\end{aligned}$$

Multiplication

Consider the numbers $a \times 10^{y}$ and $b \times 10^{z}$. Their product is $a \times b \times 10^{(y+z)}$. *Coefficients are multiplied, and exponents are added.*

$$\begin{aligned}0.0220 \times 0.0040 \times 750 &= (2.20 \times 10^{-2})(4.0 \times 10^{-3})(7.5 \times 10^{2}) \\ &= (2.20 \times 4.0 \times 7.5) \times 10^{(-2-3+2)} = 66 \times 10^{-3} \\ &= 6.6 \times 10^{1} \times 10^{-3} = 6.6 \times 10^{-2}\end{aligned}$$

Division

Consider the numbers $a \times 10^{y}$ and $b \times 10^{z}$. Their quotient is

$$\frac{a \times 10^{y}}{b \times 10^{z}} = (a/b) \times 10^{(y-z)}$$

Coefficients are divided, and the exponent of the denominator is subtracted from the exponent of the numerator.

$$\begin{aligned}\frac{20.0 \times 636 \times 0.150}{0.0400 \times 1.80} &= \frac{(2.00 \times 10^{1})(6.36 \times 10^{2})(1.50 \times 10^{-1})}{(4.00 \times 10^{-2}) \times 1.80} \\ &= \frac{2.00 \times 6.36 \times 1.50 \times 10^{(1+2-1)}}{(4.00 \times 1.80) \times 10^{-2}} = \frac{19.1 \times 10^{2}}{7.20 \times 10^{-2}} \\ &= 2.65 \times 10^{(2-(-2))} = 2.65 \times 10^{4}\end{aligned}$$

Raising a Number to a Power

To "square" the number $a \times 10^y$ means to determine the value $(a \times 10^y)^2$, or the product $(a \times 10^y)(a \times 10^y)$. According to the rule for multiplication, this product is $(a \times a) \times 10^{(y+y)} = a^2 \times 10^{2y}$. When an exponential number is raised to a power, *the coefficient is raised to that power and the exponent is multiplied by the power*. For example,

$$(0.0034)^3 = (3.4 \times 10^{-3})^3 = (3.4)^3 \times 10^{(3)(-3)} = 39 \times 10^{-9} = 3.9 \times 10^{-8}$$

Extracting the Root of an Exponential Number

To extract the root of a number is the same as raising the number to a fractional power. This means that the square root of a number is the number to the one-half power; the cube root is the number to the one-third power; and so on. Thus,

$$\sqrt{a \times 10^y} = (a \times 10^y)^{1/2} = a^{1/2} \times 10^{y/2}$$

$$\sqrt{156} = \sqrt{1.56 \times 10^2} = (1.56)^{1/2} \times 10^{2/2} = 1.25 \times 10^1 = 12.5$$

In the following example, where the cube root is sought, the exponent (-5) is not divisible by 3; the number is rewritten with an exponent (-6) that is divisible by 3.

$$(3.52 \times 10^{-5})^{1/3} = (35.2 \times 10^{-6})^{1/3} = (35.2)^{1/3} \times 10^{-6/3} = 3.28 \times 10^{-2}$$

A-2 Logarithms

The *common* logarithm (log) of a number (N) is the exponent (x) to which the base 10 must be raised to yield the number N. That is, $\log N = x$ means that $N = 10^x = 10^{\log N}$. For simple powers of ten, for example,

$$\log 1 = \log 10^0 = 0$$

$$\log 10 = \log 10^1 = 1 \qquad \log 0.10 = \log 10^{-1} = -1$$

$$\log 100 = \log 10^2 = 2 \qquad \log 0.01 = \log 10^{-2} = -2$$

Most of the numbers that result from measurements and appear in calculations are not simple powers of 10, but it is not difficult to obtain logarithms of these numbers with an electronic calculator. To find the logarithm of a number, enter the number, followed by the "LOG" key.

$$\log 734 = 2.866$$

$$\log 0.0150 = -1.824$$

Another common example requires us to find the number having a certain logarithm. This number is often called the *antilogarithm* or the *inverse* logarithm. For example, if $\log N = 4.350$, what is N? N, the antilogarithm, is simply $10^{4.350}$, and to find its value we enter 4.350, followed by the key "10^x". Depending on the calculator used, it is usually necessary to press the key "INV" or "2nd F" before the log key.

$$\log N = 4.350$$

$$N = 10^{4.350}$$

$$N = 2.24 \times 10^4$$

If the task is to find the antilogarithm of -4.350, we again note that $N = 10^{-4.350}$, and $N = 4.47 \times 10^{-5}$. The required keystrokes on a typical electronic calculator are

$$\boxed{4}\,\boxed{.}\,\boxed{3}\,\boxed{5}\,\boxed{0}\,\boxed{\pm}\,\boxed{\text{INV}}\,\boxed{\log}$$

and the display, to three significant figures, is

$$\boxed{4.47^{-05}}$$

Some Useful Relationships

From the definition of a logarithm we can write $M = 10^{\log M}$, $N = 10^{\log N}$, and $M \times N = 10^{\log(M \times N)}$. This means that

$$\log(M \times N) = \log M + \log N$$

Similarly, it is not difficult to show that

$$\log \frac{M}{N} = \log M - \log N$$

Finally, because $N^2 = N \times N$, $10^{\log N^2} = 10^{\log N} \times 10^{\log N}$, and

$$\log N^2 = \log N + \log N = 2 \log N$$

Or, in more general terms,

$$\log N^a = a \log N$$

This expression is especially useful for extracting the roots of numbers. Thus, to determine $(2.5 \times 10^{-8})^{1/5}$, we write

$$\log(2.5 \times 10^{-8})^{1/5} = \tfrac{1}{5} \log(2.5 \times 10^{-8}) = \tfrac{1}{5}(-7.60) = -1.52$$
$$(2.5 \times 10^{-8})^{1/5} = 10^{-1.52} = 0.030$$

Significant Figures in Logarithms

To establish the number of significant figures to use in a logarithm or antilogarithm, use this fundamental rule: All digits to the *right* of the decimal point in a logarithm are significant. Digits to the *left* are used to establish the power of 10. Thus, the logarithm −2.08 is expressed to *two* significant figures. The antilogarithm of −2.08 should also be expressed to *two* significant figures; it is 8.3×10^{-3}. To help settle this point, take the antilogarithms of −2.07, −2.08, and −2.09. You will find these antilogs to be 8.5×10^{-3}, 8.3×10^{-3}, and 8.1×10^{-3}, respectively. Only *two* significant figures are justified.

Natural Logarithms

Logarithms can be expressed to a base other than 10. For instance, because $2^3 = 8$, $\log_2 8 = 3$ (read as, "the logarithm of 8 to the base 2 is equal to 3"). Similarly, $\log_2 10 = 3.322$. Several equations in this text are derived by the methods of calculus and involve logarithms. These equations require that the logarithm be a "natural" one. A *natural* logarithm has the base $e = 2.71828\ldots$. A logarithm to the base "*e*" is usually denoted as *ln*.

The relationship between a "natural" and "common" logarithm simply involves the factor $\log_e 10 = 2.303$. That is, for the number N, $\ln N = 2.303 \log N$. The methods and relationships described for logarithms and antilogarithms to the base 10 all apply to the base *e* as well, except that the relevant keys on an electronic calculator are "ln" and "e^x" rather than "LOG" and "10^x."

A-3 Algebraic Operations

An algebraic equation is solved when one of the quantities, the unknown, is expressed in terms of all the other quantities in the equation. This effect is achieved when the unknown is present, *alone*, on one side of the equation, and the rest of the terms are on the other side. To solve an equation, a rearrangement of terms may be necessary. The basic principle governing these rearrangements is quite simple. *Whatever is done to one side of the equation must be done to the other as well.*

$3x^2 + 6 = 33$	***Solve for x.***
$3x^2 + \cancel{6} - \cancel{6} = 33 - 6$	(1) Subtract 6 from each side.
$3x^2 = 27$	
$\dfrac{3x^2}{3} = \dfrac{27}{3}$	(2) Divide each side by 3.
$x^2 = 9$	
$\sqrt{x^2} = \sqrt{9}$	(3) Extract the square root of each side.
$x = 3$	(4) Simplify. The square root of 9 is 3.

Quadratic Equations

A quadratic equation has the form $ax^2 + bx + c = 0$, where a, b, and c are constants (a cannot be equal to 0). A number of calculations in the text require us to solve a quadratic equation. At times, quadratic equations are of the form

$$(x + n)^2 = m^2$$

Such equations can be solved by extracting the square root of each side.

$$x + n = \pm m \quad \text{and} \quad x = m - n \quad \text{or} \quad x = -m - n$$

More likely, however, the *quadratic formula* will be needed.

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

In Example 15-13 on page 685, the following equation must be solved.

$$\frac{(0.300 - x)}{(0.200 + x)(0.100 + x)} = 2.98$$

This is a quadratic equation, but before the quadratic formula can be applied, the equation must be rearranged to the standard form: $ax^2 + bx + c = 0$. This is accomplished in the steps that follow.

$$\begin{aligned}(0.300 - x) &= 2.98(0.200 + x)(0.100 + x)\\ 0.300 - x &= 2.98(0.0200 + 0.300x + x^2)\\ 0.300 - x &= 0.0596 + 0.894x + 2.98x^2\end{aligned}$$

$$2.98x^2 + 1.894x - 0.240 = 0 \tag{A.1}$$

Now we can apply the quadratic formula.

$$\begin{aligned}x &= \frac{-1.894 \pm \sqrt{(1.894)^2 + (4 \times 2.98 \times 0.240)}}{2 \times 2.98}\\ &= \frac{-1.894 \pm \sqrt{3.587 + 2.86}}{2 \times 2.98}\\ &= \frac{-1.894 \pm \sqrt{6.45}}{2 \times 2.98} = \frac{-1.894 \pm 2.54}{2 \times 2.98}\\ &= \frac{-1.894 + 2.54}{2 \times 2.98} = \frac{0.65}{5.96} = 0.11\end{aligned}$$

Note that only the $(+)$ value of the $(\pm)$ sign was used in solving for x. If the $(-)$ value had been used, a negative value of x would have resulted. However, for the given situation a negative value of x is meaningless.

The Method of Successive Approximations

The quadratic equation that was just solved using the quadratic formula can be solved by an alternative method that can be extended to equations of higher order, such as the cubic, quartic, and quintic equations often encountered in solving equilibrium problems. To illustrate the method suppose we wish to solve expression (A.1) without recourse to the quadratic formula. We can rewrite the equation as follows

$$x = \frac{2.98x^2 - 0.240}{-1.894}$$

and make a guess at the value of x, which we substitute into the right hand side of the equation to calculate a new value of x. If we guess 0.15, which is reasonable given the starting concentrations involved in Example 15-13, we calculate

$$x = \frac{2.98 \times (0.15)^2 - 0.240}{-1.894} = 0.091$$

We can now use this value of x to calculate a new one.

$$x = \frac{2.98 \times (0.091)^2 - 0.240}{-1.894} = 0.114$$

Repeating this procedure one more time, we get

$$x = \frac{2.98 \times (0.114)^2 - 0.240}{-1.894} = 0.106$$

One more attempt gives a value of 0.11, which is in agreement with the answer previously obtained. The method that we have just used is called the method of successive approximations.

Let us now apply the method of successive approximations to the equation obtained in the Integrative Example of Chapter 15, namely

$$256x^5 - 0.74[(1.00 - x)(1.00 - 2x)^2] = 0 \qquad \textbf{(A.2)}$$

The approach we can take here is to guess a value of x; evaluate the expression to see how close to zero it comes; and then adjust the value of x accordingly. Let us start with a guess of 0.40. The result is

$$256(0.40)^5 - 0.74[(1.00 - 0.40)(1.00 - 2 \times 0.40)^2] = 2.60$$

Clearly the value of 0.40 is too large. If we now try 0.10 we obtain a value of -0.42. We have overshot the value of x. We can now try a value of 0.25 (halfway between our two previous guesses) and obtain 0.11. We realize now that we have to reduce the guessed value of x slightly to get closer to zero. If we try 0.20 we obtain -0.13, and if we next try the value $x = 0.225$ we obtain -0.03. We are now very close to our goal of finding the value of x that satisfies the expression. One final guess of 0.23 gives a value of -0.001, a very satisfactory result.

An alternative approach is to rewrite expression (A.2) as

$$x^5 = \frac{0.74[(1.00 - x)(1.00 - 2x)^2]}{256}$$

and evaluate x as the fifth root of this new expression. If we substitute a value of $x = 0.40$ on the right side, we obtain $x = 0.15$ on the left side. Now by using this value on the right we calculate a new value of $x = 0.26$ on the left. By using this value we obtain $x = 0.22$ on the left, and finally with this last value we obtain $x = 0.23$, in agreement with our previous procedure. Which method we use is a matter of convenience, but the second method provides a new value of x whereas the first method may require more trial and error. When using the method of successive approximations, it is often a useful strategy to take the average of two results in order to speed up the convergence. The method of successive approximations can be very useful, but sometimes, depending how the equation is set up, the convergence to the correct answer may be slow or the process may even diverge. In such circumstances, the expression can be graphed as a function of x to ascertain where the solutions occur. In any event, we must always make sure that any answer obtained is reasonable from a chemical or physical point of view.

A-4 Graphs

Suppose the following sets of numbers are obtained for two quantities x and y by laboratory measurement.

$$x = 0, 1, 2, 3, 4, \ldots$$

$$y = 2, 4, 6, 8, 10, \ldots$$

The relationship between these sets of numbers is not difficult to establish.

$$y = 2x + 2$$

Ideally, the results of experimental measurements are best expressed through a mathematical equation. Sometimes, however, an exact equation cannot be written, or its form is not clear from the experimental data. The graphing of data is very useful in such cases. In Figure A-1 the points listed above are located on a coordinate grid in which x values are placed along the horizontal axis (abscissa) and y values along the vertical axis (ordinate). For each point the x and y values are indicated in parentheses.

The data points are seen to define a straight line. A mathematical equation of a straight line has the form

$$y = mx + b$$

Values of m, the *slope* of the line, and b, the *intercept*, can be obtained from the straight-line graph.

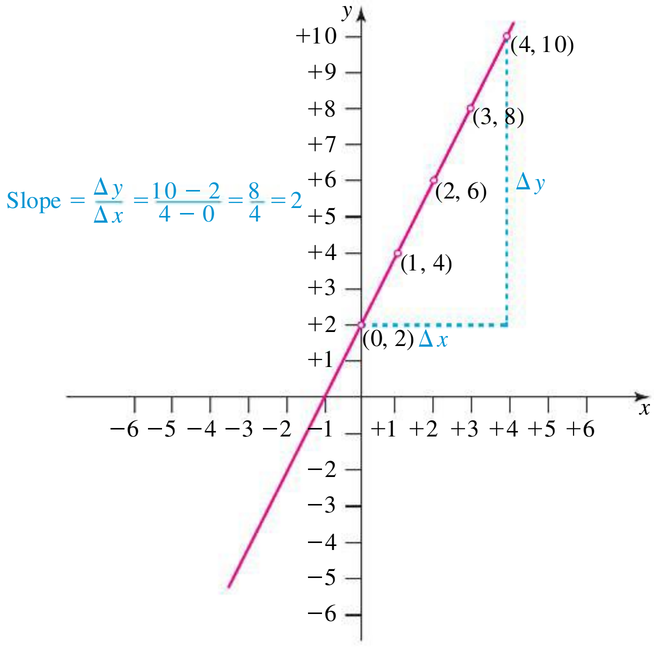
When $x = 0$, $y = b$. The intercept is the point where the straight line intersects the y-axis. The slope can be obtained from two points on the graph.

$$y_2 = mx_2 + b \quad \text{and} \quad y_1 = mx_1 + b$$

$$y_2 - y_1 = m(x_2 - x_1) + \cancel{b} - \cancel{b}$$

$$m = \frac{y_2 - y_1}{x_2 - x_1}$$

From the straight line in Figure A-1, can you establish that $m = b = 2$?



▲ FIGURE A-1
A straight-line graph: $y = mx + b$

The technique used above to eliminate the constant b is applied to logarithmic functions in several places in the text. For example, the expression written below is from page 516. In this expression P is a pressure, T is a Kelvin temperature, and A and B are constants. The equation is that of a straight line.

equation of straight line:

$$\underset{y}{\underbrace{\ln P}} = \underset{m\,\times\,x}{-A\left(\frac{1}{T}\right)} + \underset{b}{B}$$

We can write this equation twice, for the point (P_1,T_1) and the point (P_2,T_2).

$$\ln P_1 = -A\left(\frac{1}{T_1}\right) + B \quad \text{and} \quad \ln P_2 = -A\left(\frac{1}{T_2}\right) + B$$

The difference between these equations is

$$\ln P_2 - \ln P_1 = -A\left(\frac{1}{T_2}\right) + \cancel{B} + A\left(\frac{1}{T_1}\right) - \cancel{B}$$

$$\ln\frac{P_2}{P_1} = A\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

A-5 Using Conversion Factors (Dimensional Analysis)

Some calculations in general chemistry require that a quantity measured in one set of units be converted to another set of units. Consider this fact.

$$1\text{ m} = 100\text{ cm}$$

Divide each side of the equation by 1 m.

$$\frac{1\ \cancel{\text{m}}}{1\ \cancel{\text{m}}} = \frac{100\text{ cm}}{1\text{ m}}$$

On the left side of the equation, the numerator and denominator are identical; they cancel.

$$1 = \frac{100\text{ cm}}{1\text{ m}} \tag{A.3}$$

On the right side they are not identical, but they are equal because they do represent the *same length*. The ratio 100 cm/1 m, when multiplied by a length in meters, converts that length to centimeters. The ratio is called a *conversion factor*.

Consider the question, "how many centimeters are there in 6.22 m?" The measured quantity is 6.22 m, and multiplying this quantity by 1 does not change its value.

$$6.22\text{ m} \times 1 = 6.22\text{ m}$$

Now replace the factor "1" by its equivalent—the conversion factor (A.3). Cancel the unit, m, and carry out the multiplication.

$$6.22\ \cancel{\text{m}} \times \underbrace{\frac{100\text{ cm}}{1\ \cancel{\text{m}}}}_{\substack{\text{this factor}\\ \text{converts}\\ \text{m to cm}}} = 622\text{ cm}$$

Next consider the question, "how many meters are there in 576 cm?" If we use the same factor (A.3) as before, the result is nonsensical.

$$576\text{ cm} \times \frac{100\text{ cm}}{1\text{ m}} = 5.76 \times 10^4\text{ cm}^2/\text{m}$$

Factor (A.3) must be rearranged to 1 m/100 cm.

$$576\ \cancel{\text{cm}} \times \underbrace{\frac{1\ \text{m}}{100\ \cancel{\text{cm}}}}_{\substack{\text{this factor}\\ \text{converts}\\ \text{cm to m}}} = 5.76\ \text{m}$$

This second example emphasizes two points.

1. There are two ways to write a conversion factor—in one form or its reciprocal (inverse). Because a conversion factor is equal to 1, its value is not changed by the inversion, but:
2. A conversion factor must be used in such a way as to produce the necessary cancellation of units.

Calculations based on conversion factors are always of the form

◀ Because of the importance of the cancellation of units, this problem-solving method is often called *unit analysis* or *dimensional analysis.*

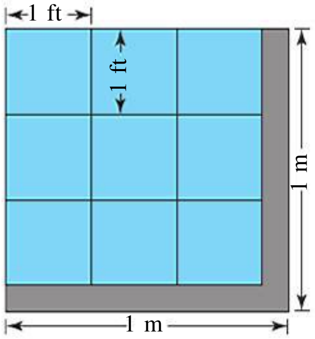
$$\textit{information sought} = \textit{information given} \times \textit{conversion factor(s)} \qquad \textbf{(A.4)}$$

Often several conversions must be made in sequence in order to get to the desired result. For example, if we want to know how many yards (yd) there are in 576 cm, we find that there is no direct cm → yd conversion factor available. From the inside back cover of the text, however, we do find a conversion factor for cm → in. Thus, we can develop a *conversion pathway*, that is, a series of conversion factors that will take us from centimeters to yards:

$$\text{cm} \rightarrow \text{in.} \rightarrow \text{ft} \rightarrow \text{yd}$$

$$\begin{aligned} ?\ \text{yards} &= 576\ \cancel{\text{cm}} \times \frac{1\ \cancel{\text{in.}}}{2.54\ \cancel{\text{cm}}} \times \frac{1\ \cancel{\text{ft}}}{12\ \cancel{\text{in.}}} \times \frac{1\ \text{yd}}{3\ \cancel{\text{ft}}} \\ &= 6.30\ \text{yd} \end{aligned}$$

We can use the same idea of a conversion pathway to deal with the somewhat more challenging situation faced when the units are squared (or cubed). Consider the question, "how many square feet (ft^2) correspond to an area of 1.00 square meter (m^2), given that 1 m = 39.37 in and 12 in = 1 ft?" Here, it may be helpful to begin by drawing a sketch or outline of the situation. Figure A-2 represents an area of 1.00 m^2. Think of it as a square with sides 1 m long. Figure A-2 also represents the length 1 ft and an area of 1.00 ft^2. Do you see that there is somewhat more than 9 ft^2 in 1 m^2?



▲ FIGURE A-2
Comparison of one square foot and one square meter
One meter is slightly longer than 3 ft; 1 m^2 is somewhat larger than 9 ft^2.

We can write expression (A.4) as follows:

$$?\ \text{ft}^2 = 1.00\ \text{m}^2 \times \underbrace{\left(\frac{39.37\ \text{in.}}{1\ \text{m}}\right)\left(\frac{39.37\ \text{in.}}{1\ \text{m}}\right)}_{\substack{\text{to convert}\\ \text{m}^2 \text{ to in}^2}} \times \underbrace{\left(\frac{1\ \text{ft}}{12\ \text{in.}}\right)\left(\frac{1\ \text{ft}}{12\ \text{in.}}\right)}_{\substack{\text{to convert}\\ \text{in}^2 \text{ to ft}^2}}$$

This is the same as writing

$$?\ \text{ft}^2 = 1.00\ \cancel{\text{m}^2} \times \frac{(39.37)^2\ \cancel{\text{in.}^2}}{1\ \cancel{\text{m}^2}} \times \frac{1\ \text{ft}^2}{(12)^2\ \cancel{\text{in.}^2}} = 10.8\ \text{ft}^2$$

Another way to look at the problem is to convert the length 1.00 m to feet,

$$?\ \text{ft} = 1.00\ \cancel{\text{m}} \times \frac{39.37\ \cancel{\text{in.}}}{1\ \cancel{\text{m}}} \times \frac{1\ \text{ft}}{12\ \cancel{\text{in.}}} = 3.28\ \text{ft}$$

and square the result

$$?\ \text{ft}^2 = 3.28\ \text{ft} \times 3.28\ \text{ft} = 10.8\ \text{ft}^2$$

Our last example incorporates several ideas discussed above. Here we will examine the situation in which the units in both the numerator and denominator must be converted. Consider the question, "how many meters per second (m/s) correspond to a speed of 63 mph, given that 1 mi = 5280 ft?"

We need to convert from miles to meters in the numerator and from hours to seconds in the denominator. We will need to use conversion factors from elsewhere in Section A-5 in addition to the given value. Also, we must be careful that our conversion factors produce the correct cancellation of units.

$$? \, \frac{\text{m}}{\text{s}} = \frac{63 \, \cancel{\text{mi}}}{1 \, \cancel{\text{h}}} \times \frac{1 \, \cancel{\text{h}}}{60 \, \cancel{\text{min}}} \times \frac{1 \, \cancel{\text{min}}}{60 \, \text{s}} \times \frac{5280 \, \cancel{\text{ft}}}{1 \, \cancel{\text{mi}}} \times \frac{12 \, \cancel{\text{in.}}}{1 \, \cancel{\text{ft}}} \times \frac{1 \, \text{m}}{39.37 \, \cancel{\text{in.}}}$$

$$= 28 \, \frac{\text{m}}{\text{s}}$$

In an alternative approach we break down the problem into three steps: (1) Convert 63 miles to a distance in meters; (2) convert 1 hour to a time in seconds; and (3) express the speed as a ratio of distance over time.

Step 1.

$$\text{distance} = 63 \, \cancel{\text{mi}} \times \frac{5280 \, \cancel{\text{ft}}}{1 \, \cancel{\text{mi}}} \times \frac{12 \, \cancel{\text{in.}}}{1 \, \cancel{\text{ft}}} \times \frac{1 \, \text{m}}{39.37 \, \cancel{\text{in.}}} = 1.0 \times 10^5 \, \text{m}$$

Step 2.

$$\text{time} = 1 \, \cancel{\text{h}} \times \frac{60 \, \cancel{\text{min}}}{1 \, \cancel{\text{h}}} \times \frac{60 \, \text{s}}{1 \, \cancel{\text{min}}} = 3.6 \times 10^3 \, \text{s}$$

Step 3.

$$\text{speed} = \frac{\text{distance}}{\text{time}} = \frac{1.0 \times 10^5 \, \text{m}}{3.6 \times 10^3 \, \text{s}} = 28 \, \frac{\text{m}}{\text{s}}$$

In conclusion, we have shown (1) how to make a conversion factor; (2) that a conversion factor may be inverted; (3) that a series of conversion factors may be used to make a conversion pathway; (4) that conversion factors may be raised to powers, if necessary; and (5) that conversions of values with units in both the numerator and the denominator (such as miles per hour or pounds per square inch) can be performed in one step or in several steps.

B

Appendix

Some Basic Physical Concepts

B-1 Velocity and Acceleration

Time elapses as an object moves from one point to another. The *velocity* of the object is defined as the distance traveled per unit of time. An automobile that travels a distance of 60.0 km in exactly one hour has a velocity of 60.0 km/h (or 16.7 m/s).

Table B.1 contains data on the velocity of a free-falling object. For this motion, velocity is not constant—it increases with time. The falling object "speeds up" continuously. The rate of change of velocity with time is called *acceleration*. Acceleration has the units of distance per unit time per unit time. With the methods of calculus, mathematical equations can be derived for the velocity (u) and distance (d) traveled in a time (t) by an object that has a constant acceleration (a).

$$u = at \qquad \textbf{(B.1)}$$

$$d = \tfrac{1}{2}at^2 \qquad \textbf{(B.2)}$$

For a free-falling object, the constant acceleration, called the *acceleration due to gravity*, is $a = g = 9.8\ \text{m/s}^2$. Equations (B.1) and (B.2) can be used to calculate the velocity and distance traveled by a free-falling object.

TABLE B.1 Velocity and Acceleration of a Free-Falling Body

Time Elapsed, s	Total Distance, m	Velocity, m/s	Acceleration, m/s^2
0	0		
		4.9	
1	4.9		9.8
		14.7	
2	19.6		9.8
		24.5	
3	44.1		9.8
		34.3	
4	78.4		

B-2 Force and Work

Newton's *first law* of motion states that an object at rest remains at rest, and that an object in motion remains in uniform motion unless acted upon by an external force. The tendency for an object to remain at rest or in uniform motion is called *inertia; a force* is what is required to overcome inertia. Since the application of a force either gives an object motion or changes its motion, the actual effect of a force is to change the velocity of an object. Change in velocity is an *acceleration*, so force is what provides an object with acceleration.

Newton's *second law* of motion describes the force F required to produce an acceleration a in an object of mass m.

$$F = ma \tag{B.3}$$

The basic unit of force in the SI system is the *newton* (N). It is the force required to provide a one-kilogram mass with an acceleration of one meter per second per second.

$$1\text{ N} = 1\text{ kg} \times 1\text{ m s}^{-2} \tag{B.4}$$

The force of gravity on an object (its weight) is the product of the mass of the object and the acceleration due to gravity, g.

$$F = mg \tag{B.5}$$

Work (w) is performed when a force acts through a distance.

$$\text{work}\,(w) = \text{force}\,(F) \times \text{distance}\,(d) \tag{B.6}$$

The *joule* (J) is the amount of work associated with a force of one newton (N) acting through a distance of one meter.

$$1\text{ J} = 1\text{ N} \times 1\text{ m} \tag{B.7}$$

From the definition of the newton in expression (B.4), we can also write

$$1\text{ J} = 1\text{ kg} \times 1\text{ m s}^{-2} \times 1\text{ m} = 1\text{ kg m}^2\text{ s}^{-2} \tag{B.8}$$

B-3 Energy

Energy is defined as the capacity to do work, but there are other useful descriptions of energy as well. For example, a moving object possesses a kind of energy known as *kinetic energy*. We can obtain a useful equation for kinetic energy by combining some of the other simple equations in this appendix. Thus, because work is the product of a force and distance (equation B.6), and force is the product of a mass and acceleration (equation B.3), we can write

$$w\,(\text{work}) = m \times a \times d \tag{B.9}$$

Now, if we substitute equation (B.2) relating acceleration (a), distance (d), and time (t), into equation (B.9), we obtain

$$w\,(\text{work}) = m \times a \times \frac{1}{2}at^2 \tag{B.10}$$

Finally, let's substitute expression (B.1) relating acceleration (a) and velocity (u) into (B.10). That is, because $a = u/t$,

$$w\,(\text{work}) = \frac{1}{2}m\left(\frac{u}{t}\right)^2 t^2 \tag{B.11}$$

Think of the work in (B.11) as the amount of work necessary to produce a velocity of u in an object of mass m. This amount of work is the energy that appears in the object as kinetic energy (e_k).

$$e_k\,(\text{kinetic energy}) = \frac{1}{2}mu^2 \tag{B.12}$$

An object at rest may also have the capacity to do work by changing its position. The energy it possesses, which can be transformed into actual work, is called *potential energy*. Think of potential energy as energy "stored" within an object. Equations can be written for potential energy, but the exact forms of these equations depend on the manner in which the energy is "stored."

B-4 Magnetism

Attractive and repulsive forces associated with a magnet are centered at regions called *poles*. A magnet has a north and a south pole. If two magnets are aligned such that the north pole of one is directed toward the south pole of the second, an attractive force develops. If the alignment brings like poles into proximity, either both north or both south, a repulsive force develops. *Unlike poles attract; like poles repel.*

A *magnetic field* exists in that region surrounding a magnet in which the influence of the magnet can be felt. Internal changes produced within an iron object by a magnetic field, not produced in a field-free region, are responsible for the attractive force that the object experiences.

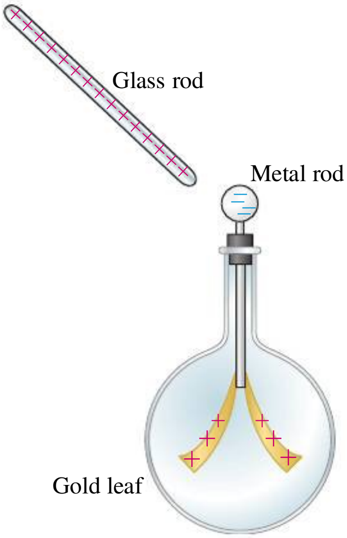
B-5 Static Electricity

Another property with which certain objects may be endowed is *electric charge*. Analogous to the case of magnetism, *unlike charges attract, and like charges repel* (recall Figure 2-4). The unit of charge is called a *coulomb*, C. In Coulomb's law, stated below, a *positive* force between electrically charged objects is *repulsive; a negative* force is *attractive*.

$$F = \frac{Q_1 Q_2}{4\pi\varepsilon r^2} \tag{B.13}$$

where Q_1 is the charge on object 1,
Q_2 is the charge on object 2,
r is the distance between the objects, and
ε is a proportionality constant called the *dielectric constant*, whose numerical value reflects the effect that the medium separating two charged objects has on the force existing between them. For a vacuum, $\varepsilon = \varepsilon_0 = 8.85419 \times 10^{-12}\,\mathrm{C^2\,N^{-1}\,m^{-2}} = 8.85419 \times 10^{-12}\,\mathrm{C^2\,J^{-1}\,m^{-1}}$; for other media, ε_0 is greater than 1 (for example, for water $\varepsilon = 78.5\varepsilon_0$).

An *electric field* exists in that region surrounding an electrically charged object in which the influence of the electric charge is felt. If an uncharged object is brought into the field of a charged object, the uncharged object may undergo internal changes that it would not experience in a field-free region. These changes may lead to the production of electric charges in the formerly uncharged object, a phenomenon called *induction* (illustrated in Figure B-1).



◀ FIGURE B-1
Production of electric charges by induction in a gold-leaf electroscope
The glass rod acquires a positive electric charge by being rubbed with a silk cloth. As the rod is brought near the electroscope, a separation of charge occurs in the electroscope. The leaves become positively charged and repel one another. Negative charge is attracted to the spherical terminal at the end of the metal rod. If the glass rod is removed, the charges on the electroscope redistribute themselves, and the leaves collapse. If the spherical ball is touched by an electric conductor before the glass rod is removed, negative charge is removed from the ball. The electroscope retains a net positive charge, and the leaves remain outstretched.

The potential energy (*PE*) associated with the interaction of two charged objects is given by

$$PE = \frac{Q_1 Q_2}{4\pi\varepsilon r} \qquad \textbf{(B.14)}$$

PE is equal to the work done when the distance between the two objects is decreased from infinity to *r*.

B-6 Current Electricity

Current electricity is a flow of electrically charged particles. In electric currents in metallic conductors, the charged particles are electrons; in molten salts or in aqueous solutions, the particles are both negatively and positively charged ions.

As pointed out in Section B-5, the unit of electric charge is called a *coulomb* (C). The unit of electric current known as the *ampere* (A) is defined as a flow of one coulomb per second through an electrical conductor. Two variables determine the magnitude of the electric current I flowing through a conductor. These are the potential difference, or voltage drop, E, along the conductor, and the electrical resistance of the conductor, R. The units of voltage and resistance are the *volt* (V) and *ohm*, respectively. The relationship of electric current, voltage, and resistance is given by Ohm's law.

$$I = \frac{E}{R} \qquad \textbf{(B.15)}$$

One joule of energy is associated with the passage of one coulomb of electric charge through a potential difference (voltage) of one volt. That is, one joule = one volt-coulomb. Electric *power* refers to the rate of production (or consumption) of electric energy. It has the unit *watt* (W).

$$1\text{ W} = 1\text{ J s}^{-1} = 1\text{ V C s}^{-1}$$

Since one coulomb per second is a current of one ampere,

$$1\text{ W} = 1\text{ V} \times 1\text{ A} \qquad \textbf{(B.16)}$$

Thus, a 100-watt light bulb operating at 110 V draws a current of 100 W/110 V = 0.91 A.

B-7 Electromagnetism

The relationship between electricity and magnetism is an intimate one. Interactions of electric and magnetic fields result in (1) magnetic fields associated with the flow of electric current (as in electromagnets), (2) forces experienced by current-carrying conductors when placed in a magnetic field (as in electric motors), and (3) electric current being induced when an electric conductor is moved through a magnetic field (as in electric generators). Several observations described in this text can be understood in terms of electromagnetic phenomena.

C

Appendix

SI Units

The system of units that will in time be used universally for expressing all measured quantities is Le Système International d'Unités (The International System of Units), adopted in 1960 by the Conference Générale des Poids et Measures (General Conference of Weights and Measures). A summary of some of the provisions of the SI convention is provided here.

C-1 SI Base Units

A single unit has been established for each of the basic quantities involved in measurement. These are as follows:

Physical Quantity	Unit	Symbol
Length	Meter	m
Mass	Kilogram	kg
Time	Second	s
Electric current	Ampere	A
Temperature	Kelvin	K
Luminous intensity	Candela	cd
Amount of substance	Mole	mol
Plane angle	Radian	rad
Solid angle	Steradian	sr

C-2 SI Prefixes

Distinctive prefixes are attached to the base unit to express quantities that are *multiples* (greater than) or *submultiples* (less than) of the base unit. The multiples and submultiples are obtained by multiplying the base unit by powers of ten.

Multiple	Prefix	Symbol	Submultiple	Prefix	Symbol
10^{12}	tera	T	10^{-1}	deci	d
10^{9}	giga	G	10^{-2}	centi	c
10^{6}	mega	M	10^{-3}	milli	m
10^{3}	kilo	k	10^{-6}	micro	μ
10^{2}	hecto	h	10^{-9}	nano	n
10^{1}	deka	da	10^{-12}	pico	p
			10^{-15}	femto	f
			10^{-18}	atto	a

C-3 Derived SI Units

A number of quantities must be derived from measured values of the SI base quantities [for example, volume has the unit $(\text{length})^3$]. Two sets of derived units are given, those whose names follow directly from the base units and those that are given special names. Notice that the units used in the text differ in some respects from those in the table. For example, for the most part, the text expresses density as g cm^{-3}, molar mass as g mol^{-1}, molar volume as mL mol^{-1} or L mol^{-1}, and molar concentration (molarity) as mol L^{-1}, or M.

▶ Two other SI conventions are illustrated through this table: (a) Units are written in singular form—meter or m, *not* meters or ms; (b) negative exponents are preferred to the shilling bar or solidus (/), that is, m s^{-1} and m s^{-2}, *not* m/s and m/s/s. In some chapters both ways of expressing units have been used as you need to be comfortable with both systems.

Physical Quantity	Unit	Symbol
Area	Square meter	m^2
Volume	Cubic meter	m^3
Velocity	Meter per second	$\mathrm{m\ s}^{-1}$
Acceleration	Meter per second squared	$\mathrm{m\ s}^{-2}$
Density	Kilogram per cubic meter	$\mathrm{kg\ m}^{-3}$
Molar mass	Kilogram per mole	$\mathrm{kg\ mol}^{-1}$
Molar volume	Cubic meter per mole	$\mathrm{m}^3\ \mathrm{mol}^{-1}$
Molar concentration	Mole per cubic meter	$\mathrm{mol\ m}^{-3}$

Physical Quantity	Unit	Symbol	In Terms of SI Units
Frequency	hertz	Hz	s^{-1}
Force	newton	N	$\mathrm{kg\ m\ s}^{-2}$
Pressure	pascal	Pa	$\mathrm{N\ m}^{-2}$
Energy	joule	J	$\mathrm{kg\ m}^2\ \mathrm{s}^{-2}$
Power	watt	W	$\mathrm{J\ s}^{-1}$
Electric charge	coulomb	C	A s
Electric potential difference	volt	V	$\mathrm{J\ A}^{-1}\ \mathrm{s}^{-1}$
Electric resistance	ohm	Ω	$\mathrm{V\ A}^{-1}$

C-4 Units to Be Discouraged or Abandoned

There are several commonly used units whose use is to be discouraged and ultimately abandoned. Their gradual disappearance is to be expected, though each is used in this text. A few such units are listed.

▶ Another SI convention is implied here. No commas are used in expressing large numbers. Instead, spaces are left between groupings of three digits, that is, 101 325 rather than 101,325. Decimal points are written either as periods or commas. Numbers in this text retained the comma separators in numbers of at least five digits.

Physical Quantity	Unit	Symbol	Definition of SI Units
Length	ångstrom	Å	1×10^{-10} m
Force	dyne	dyn	1×10^{-5} N
Energy	erg	erg	1×10^{-7} J
Energy	calorie	cal	4.184 J
Pressure	atmosphere	atm	101 325 Pa
Pressure	millimeter of mercury	mmHg	133.322 Pa
Pressure	torr	Torr	133.322 Pa

36	Kr	[Ar] $3d^{10}4s^24p^6$						

The electron configurations printed in red are those of the noble gases. Each noble gas configuration serves as the core of the electron configurations of the elements that follow it, until the next noble gas is reached. Thus, [He] represents the core configuration of the second period elements; [Ne], the third period; [Ar], the fourth period; [Kr], the fifth period; [Xe], the sixth period; and [Rn], the seventh period.

TABLE D.2 Thermodynamic Properties of Substances at 298.15 K*. Substances are at 1 bar pressure. For aqueous solutions, solutes are at unit activity (roughly 1 M). Data for ions in aqueous solution are relative to values of *zero* for ΔH_f°, ΔG_f°, and S° for H^+

*Data for inorganic substances and for organic compounds with up to two carbon atoms per molecule are adapted from D. D. Wagman, et al., "The NBS Tables of Chemical Thermodynamic Properties: Selected Values for Inorganic and C_1 and C_2 Organic Substances in SI Units" *Journal of Physical and Chemical Reference Data* 11 (1982) Supplement 2. Data for other organic compounds are from J. A. Dean, *Lange's Handbook of Chemistry*. 15th ed., McGraw-Hill, 1999, and other sources.

TABLE D.3 Equilibrium Constants

A. Ionization Constants of Weak Acids at 25 °C

Name of acid	Formula	K_a	Name of acid	Formula	K_a
Acetic	$HC_2H_3O_2$	1.8×10^{-5}	Hyponitrous	$HON{=}NOH$	8.9×10^{-8}
Acrylic	$HC_3H_3O_2$	5.5×10^{-5}		$HON{=}NO^-$	4×10^{-12}
Arsenic	H_3AsO_4	6.0×10^{-3}	Iodic	HIO_3	1.6×10^{-1}
	$H_2AsO_4^-$	1.0×10^{-7}	Iodoacetic	$HC_2H_2IO_2$	6.7×10^{-4}
	$HAsO_4^{2-}$	3.2×10^{-12}	Malonic	$H_2C_3H_2O_4$	1.5×10^{-3}
Arsenous	H_3AsO_3	6.6×10^{-10}		$HC_3H_2O_4^-$	2.0×10^{-6}
Benzoic	$HC_7H_5O_2$	6.3×10^{-5}	Nitrous	HNO_2	7.2×10^{-4}
Bromoacetic	$HC_2H_2BrO_2$	1.3×10^{-3}	Oxalic	$H_2C_2O_4$	5.4×10^{-2}
Butyric	$HC_4H_7O_2$	1.5×10^{-5}		$HC_2O_4^-$	5.3×10^{-5}
Carbonic	H_2CO_3	4.4×10^{-7}	Phenol	HOC_6H_5	1.0×10^{-10}
	HCO_3^-	4.7×10^{-11}	Phenylacetic	$HC_8H_7O_2$	4.9×10^{-5}
Chloroacetic	$HC_2H_2ClO_2$	1.4×10^{-3}	Phosphoric	H_3PO_4	7.1×10^{-3}
Chlorous	$HClO_2$	1.1×10^{-2}		$H_2PO_4^-$	6.3×10^{-8}
Citric	$H_3C_6H_5O_7$	7.4×10^{-4}		HPO_4^{2-}	4.2×10^{-13}
	$H_2C_6H_5O_7^-$	1.7×10^{-5}	Phosphorous	H_3PO_3	3.7×10^{-2}
	$HC_6H_5O_7^{2-}$	4.0×10^{-7}		$H_2PO_3^-$	2.1×10^{-7}
Cyanic	$HOCN$	3.5×10^{-4}	Propionic	$HC_3H_5O_2$	1.3×10^{-5}
Dichloroacetic	$HC_2HCl_2O_2$	5.5×10^{-2}	Pyrophosphoric	$H_4P_2O_7$	3.0×10^{-2}
Fluoroacetic	$HC_2H_2FO_2$	2.6×10^{-3}		$H_3P_2O_7^-$	4.4×10^{-3}
Formic	$HCHO_2$	1.8×10^{-4}		$H_2P_2O_7^{2-}$	2.5×10^{-7}
Hydrazoic	HN_3	1.9×10^{-5}		$HP_2O_7^{3-}$	5.6×10^{-10}
Hydrocyanic	HCN	6.2×10^{-10}	Selenic	H_2SeO_4	strong acid
Hydrofluoric	HF	6.6×10^{-4}		$HSeO_4^-$	2.2×10^{-2}
Hydrogen peroxide	H_2O_2	2.2×10^{-12}	Selenous	H_2SeO_3	2.3×10^{-3}
Hydroselenic	H_2Se	1.3×10^{-4}		$HSeO_3^-$	5.4×10^{-9}
	HSe^-	1×10^{-11}	Succinic	$H_2C_4H_4O_4$	6.2×10^{-5}
Hydrosulfuric	H_2S	1.0×10^{-7}		$HC_4H_4O_4^-$	2.3×10^{-6}
	HS^-	1×10^{-19}	Sulfuric	H_2SO_4	strong acid
Hydrotelluric	H_2Te	2.3×10^{-3}		HSO_4^-	1.1×10^{-2}
	HTe^-	1.6×10^{-11}	Sulfurous	H_2SO_3	1.3×10^{-2}
Hypobromous	$HOBr$	2.5×10^{-9}		HSO_3^-	6.2×10^{-8}
Hypochlorous	$HOCl$	2.9×10^{-8}	Thiophenol	HSC_6H_5	3.2×10^{-7}
Hypoiodous	HOI	2.3×10^{-11}	Trichloroacetic	$HC_2Cl_3O_2$	3.0×10^{-1}

B. Ionization Constants of Weak Bases at 25 °C

Name of base	Formula	K_b	Name of base	Formula	K_b
Ammonia	NH_3	1.8×10^{-5}	Isoquinoline	C_9H_7N	2.5×10^{-9}
Aniline	$C_6H_5NH_2$	7.4×10^{-10}	Methylamine	CH_3NH_2	4.2×10^{-4}
Codeine	$C_{18}H_{21}O_3N$	8.9×10^{-7}	Morphine	$C_{17}H_{19}O_3N$	7.4×10^{-7}
Diethylamine	$(C_2H_5)_2NH$	6.9×10^{-4}	Piperdine	$C_5H_{11}N$	1.3×10^{-3}
Dimethylamine	$(CH_3)_2NH$	5.9×10^{-4}	Pyridine	C_5H_5N	1.5×10^{-9}
Ethylamine	$C_2H_5NH_2$	4.3×10^{-4}	Quinoline	C_9H_7N	6.3×10^{-10}
Hydrazine	NH_2NH_2	8.5×10^{-7}	Triethanolamine	$C_6H_{15}O_3N$	5.8×10^{-7}
	$NH_2NH_3^+$	8.9×10^{-16}	Triethylamine	$(C_2H_5)_3N$	5.2×10^{-4}
Hydroxylamine	NH_2OH	9.1×10^{-9}	Trimethylamine	$(CH_3)_3N$	6.3×10^{-5}

(continued)

C. Solubility Product Constants[a]

Name of solute	Formula	K_{sp}	Name of solute	Formula	K_{sp}
Aluminum hydroxide	$Al(OH)_3$	1.3×10^{-33}	Lead(II) hydroxide	$Pb(OH)_2$	1.2×10^{-15}
Aluminum phosphate	$AlPO_4$	6.3×10^{-19}	Lead(II) iodide	PbI_2	7.1×10^{-9}
Barium carbonate	$BaCO_3$	5.1×10^{-9}	Lead(II) sulfate	$PbSO_4$	1.6×10^{-8}
Barium chromate	$BaCrO_4$	1.2×10^{-10}	Lead(II) sulfide[b]	PbS	3×10^{-28}
Barium fluoride	BaF_2	1.0×10^{-6}	Lithium carbonate	Li_2CO_3	2.5×10^{-2}
Barium hydroxide	$Ba(OH)_2$	5×10^{-3}	Lithium fluoride	LiF	3.8×10^{-3}
Barium sulfate	$BaSO_4$	1.1×10^{-10}	Lithium phosphate	Li_3PO_4	3.2×10^{-9}
Barium sulfite	$BaSO_3$	8×10^{-7}	Magnesium ammonium phosphate	$MgNH_4PO_4$	2.5×10^{-13}
Barium thiosulfate	BaS_2O_3	1.6×10^{-5}			
Bismuthyl chloride	$BiOCl$	1.8×10^{-31}	Magnesium carbonate	$MgCO_3$	3.5×10^{-8}
Bismuthyl hydroxide	$BiOOH$	4×10^{-10}	Magnesium fluoride	MgF_2	3.7×10^{-8}
Cadmium carbonate	$CdCO_3$	5.2×10^{-12}	Magnesium hydroxide	$Mg(OH)_2$	1.8×10^{-11}
Cadmium hydroxide	$Cd(OH)_2$	2.5×10^{-14}	Magnesium phosphate	$Mg_3(PO_4)_2$	1×10^{-25}
Cadmium sulfide[b]	CdS	8×10^{-28}	Manganese(II) carbonate	$MnCO_3$	1.8×10^{-11}
Calcium carbonate	$CaCO_3$	2.8×10^{-9}	Manganese(II) hydroxide	$Mn(OH)_2$	1.9×10^{-13}
Calcium chromate	$CaCrO_4$	7.1×10^{-4}	Manganese(II) sulfide[b]	MnS	3×10^{-14}
Calcium fluoride	CaF_2	5.3×10^{-9}	Mercury(I) bromide	Hg_2Br_2	5.6×10^{-23}
Calcium hydroxide	$Ca(OH)_2$	5.5×10^{-6}	Mercury(I) chloride	Hg_2Cl_2	1.3×10^{-18}
Calcium hydrogen phosphate	$CaHPO_4$	1×10^{-7}	Mercury(I) iodide	Hg_2I_2	4.5×10^{-29}
			Mercury(II) sulfide[b]	HgS	2×10^{-53}
Calcium oxalate	CaC_2O_4	4×10^{-9}	Nickel(II) carbonate	$NiCO_3$	6.6×10^{-9}
Calcium phosphate	$Ca_3(PO_4)_2$	2.0×10^{-29}	Nickel(II) hydroxide	$Ni(OH)_2$	2.0×10^{-15}
Calcium sulfate	$CaSO_4$	9.1×10^{-6}	Scandium fluoride	ScF_3	4.2×10^{-18}
Calcium sulfite	$CaSO_3$	6.8×10^{-8}	Scandium hydroxide	$Sc(OH)_3$	8.0×10^{-31}
Chromium(II) hydroxide	$Cr(OH)_2$	2×10^{-16}	Silver arsenate	Ag_3AsO_4	1.0×10^{-22}
Chromium(III) hydroxide	$Cr(OH)_3$	6.3×10^{-31}	Silver azide	AgN_3	2.8×10^{-9}
Cobalt(II) carbonate	$CoCO_3$	1.4×10^{-13}	Silver bromide	$AgBr$	5.0×10^{-13}
Cobalt(II) hydroxide	$Co(OH)_2$	1.6×10^{-15}	Silver carbonate	Ag_2CO_3	8.5×10^{-12}
Cobalt(III) hydroxide	$Co(OH)_3$	1.6×10^{-44}	Silver chloride	$AgCl$	1.8×10^{-10}
Copper(I) chloride	$CuCl$	1.2×10^{-6}	Silver chromate	Ag_2CrO_4	1.1×10^{-12}
Copper(I) cyanide	$CuCN$	3.2×10^{-20}	Silver cyanide	$AgCN$	1.2×10^{-16}
Copper(I) iodide	CuI	1.1×10^{-12}	Silver iodate	$AgIO_3$	3.0×10^{-8}
Copper(II) arsenate	$Cu_3(AsO_4)_2$	7.6×10^{-36}	Silver iodide	AgI	8.5×10^{-17}
Copper(II) carbonate	$CuCO_3$	1.4×10^{-10}	Silver nitrite	$AgNO_2$	6.0×10^{-4}
Copper(II) chromate	$CuCrO_4$	3.6×10^{-6}	Silver sulfate	Ag_2SO_4	1.4×10^{-5}
Copper(II) ferrocyanide	$Cu_2[Fe(CN)_6]$	1.3×10^{-16}	Silver sulfide[b]	Ag_2S	6×10^{-51}
Copper(II) hydroxide	$Cu(OH)_2$	2.2×10^{-20}	Silver sulfite	Ag_2SO_3	1.5×10^{-14}
Copper(II) sulfide[b]	CuS	6×10^{-37}	Silver thiocyanate	$AgSCN$	1.0×10^{-12}
Iron(II) carbonate	$FeCO_3$	3.2×10^{-11}	Strontium carbonate	$SrCO_3$	1.1×10^{-10}
Iron(II) hydroxide	$Fe(OH)_2$	8.0×10^{-16}	Strontium chromate	$SrCrO_4$	2.2×10^{-5}
Iron(II) sulfide[b]	FeS	6×10^{-19}	Strontium fluoride	SrF_2	2.5×10^{-9}
Iron(III) arsenate	$FeAsO_4$	5.7×10^{-21}	Strontium sulfate	$SrSO_4$	3.2×10^{-7}
Iron(III) ferrocyanide	$Fe_4[Fe(CN)_6]_3$	3.3×10^{-41}	Thallium(I) bromide	$TlBr$	3.4×10^{-6}
Iron(III) hydroxide	$Fe(OH)_3$	4×10^{-38}	Thallium(I) chloride	$TlCl$	1.7×10^{-4}
Iron(III) phosphate	$FePO_4$	1.3×10^{-22}	Thallium(I) iodide	TlI	6.5×10^{-8}
Lead(II) arsenate	$Pb_3(AsO_4)_2$	4.0×10^{-36}	Thallium(III) hydroxide	$Tl(OH)_3$	6.3×10^{-46}
Lead(II) azide	$Pb(N_3)_2$	2.5×10^{-9}	Tin(II) hydroxide	$Sn(OH)_2$	1.4×10^{-28}
Lead(II) bromide	$PbBr_2$	4.0×10^{-5}	Tin(II) sulfide[b]	SnS	1×10^{-26}
Lead(II) carbonate	$PbCO_3$	7.4×10^{-14}	Zinc carbonate	$ZnCO_3$	1.4×10^{-11}
Lead(II) chloride	$PbCl_2$	1.6×10^{-5}	Zinc hydroxide	$Zn(OH)_2$	1.2×10^{-17}
Lead(II) chromate	$PbCrO_4$	2.8×10^{-13}	Zinc oxalate	ZnC_2O_4	2.7×10^{-8}
Lead(II) fluoride	PbF_2	2.7×10^{-8}	Zinc phosphate	$Zn_3(PO_4)_2$	9.0×10^{-33}
			Zinc sulfide[b]	ZnS	2×10^{-25}

D. Complex-Ion Formation Constants[c, d]

[a] Data are at various temperatures around "room" temperature, from 18 to 25 °C.

[b] For a solubility equilibrium of the type $\mathrm{MS(s) + H_2O \rightleftharpoons M^{2+}(aq) + HS^-(aq) + OH^-(aq)}$.

[c] The ligands referred to in this table are monodentate: $\mathrm{Cl^-}$, $\mathrm{CN^-}$, $\mathrm{I^-}$, $\mathrm{NH_3}$, $\mathrm{OH^-}$, $\mathrm{SCN^-}$, $\mathrm{S_2O_3{}^{2-}}$; bidentate: ethylenediamine (en), oxalate ion (ox); tetradentate: ethylenediaminetetraacetato ion, $\mathrm{EDTA^{4-}}$.

[d] The K_f values are cumulative or overall formation constants (see page 1094).

TABLE D.4 Standard Electrode (Reduction) Potentials at 25 °C

Reduction half-reaction	$E°$, V
$\mathrm{F_2(g) + 2\,e^- \longrightarrow 2\,F^-(aq)}$	+2.866

Concept Maps

As you study chemistry by reading this book and attending class, you will encounter many ideas and concepts. The task of linking them together can be quite daunting. An effective way to accomplish this task is through "concept mapping." A concept map is a visual map presenting the relationships among a set of connected concepts and ideas. It is a tangible way to display how your mind "perceives" a particular topic. By constructing a concept map, you reflect on what you understand and what you do not understand. In a concept map, each concept, usually represented by a word or two in a box, is connected to other concept boxes by lines or arrows. A word or brief phrase adjacent to the line or arrow defines the relationship between the connected concepts. Each major concept box has lines to and from several other concept boxes, thereby generating a network, or "map."

E-1 How to Construct a Concept Map

1. To create a concept map, construct a list of facts, terms, and ideas that you think are in any way associated with the topic, based on your reading and class attendance. Start by asking yourself, what was the class or reading assignment about? The answer to this question will provide the initial (most general) concepts. The list of concepts will grow as you think further about the answer to this question. You can review the chapter summaries, which emphasize the important points of the chapters, as well as the key terms of that chapter.
2. Review the concepts in your list, and categorize them from most general to most specific. Keep in mind that several of the concepts may have the same level of generality. At other times, it may be difficult to determine the relative importance of two related concepts; to get around this dilemma, try posing the following question: Which concept can be understood without reference to the other? The answer is likely the more general concept.
3. Once the categories have been decided, center the most general concept at the top of the page, and draw a box around it.
4. Arrange the next-most-general rank of concepts below the most general concept. Draw boxes around these concepts, and draw lines linking them to the most general concept. The links should have arrowheads to show the directions in which they should be read.
5. The next step is to label the linkages with short phrases, or even single words, which properly relate the linked concepts. When you place concept 1, a linkage phrase, and concept 2 in sequence, a sensible phrase should result. For example, measurements (concept 1) generate (linkage phrase) numbers (concept 2) that have (linkage phrase) uncertainty (concept 3). The inclusion of linkage labels is important. The appropriate linkage phrase shows that you understand the relationship between the concepts.
6. Proceed down the page, adding rows of ever-more-specific concepts. The most specific concepts should end up at the bottom of your map.

7. Throughout the map, search for cross-links between closely related concepts appearing on the same line. Use dashed lines with double arrowheads to indicate the cross-links.
8. As a last step, assess the map and redraw it if necessary to produce a more logical and neat map.

Once you have constructed the map, check that a concept appears only once and that you have labeled all linkages. Finally, remember that there is no one *correct* concept map for a collection of concepts. However, some concept maps are much more effective than others at displaying the relationships among a given set of concepts.

The diagram in this appendix represents a concept map for the scientific method and measurements. Notice that the concept of SI units could be further connected to such concepts as fundamental units and derived units.

Appendix F

Glossary

Absolute configuration refers to the spatial arrangement of the groups attached to a chiral carbon atom. The two possibilities are D and L.

Accuracy is the "closeness" of a measured value to the true or accepted value of a quantity.

Acetyl group (See **acyl**.)

An **achiral** molecule has a structure that is superimposable on its mirror image. (See also **chiral**.)

An **acid** is (1) a hydrogen-containing compound that can produce hydrogen ions, H^+ (Arrhenius theory); (2) a proton donor (Brønsted–Lowry theory); (3) an atom, ion, or molecule that can accept a pair of electrons to form a covalent bond (Lewis theory).

An **acid–base indicator** is a substance used to measure the pH of a solution or to signal the equivalence point in an acid–base titration. The nonionized weak acid form has one color and the anionic form, a different color.

An **acid ionization constant, K_a**, is the equilibrium constant for the ionization reaction of a weak acid.

An **acid salt** contains an anion that can act as an acid (proton donor); examples are $NaHSO_4$ and NaH_2PO_4.

The **actinides** are a series of radioactive elements ($Z = 90 - 103$) characterized by partially filled $5f$ orbitals in their atoms.

An **activated complex** is an intermediate in a chemical reaction formed through collisions between energetic molecules. Once formed, it dissociates either into the products or back to the reactants.

Activation energy is the minimum total kinetic energy that molecules must bring to their collisions for a chemical reaction to occur.

Active sites are the locations at which catalysis occurs, whether on the surface of a heterogeneous catalyst or an enzyme.

Activity is the effective concentration of a species. It is obtained as the product of an activity coefficient and the ratio of the stoichiometric concentration or pressure to that of a reference state.

The **actual yield** is the *measured* quantity of a product obtained in a chemical reaction. (See also **theoretical yield** and **percent yield**.)

The **acyl group** is  $-\overset{\overset{\displaystyle O}{\|}}{C}-R$. If $R = H$, this is called the **formyl** group; $R = CH_3$, **acetyl**; and $R = C_6H_5$, **benzoyl**.

An **addition–elimination reaction** is the overall reaction that occurs when compounds are interconverted. It involves (1) a nucleophilic addition to the carbonyl carbon to form a tetrahedral intermediate, followed by (2) an elimination reaction that regenerates the carbonyl group.

In an **addition reaction**, a molecule adds across a double or triple bond in another molecule.

An **adduct** is a compound formed by joining together two simpler molecules through a coordinate covalent bond, such as the adduct of $AlCl_3$ and $(C_2H_5)_2O$ pictured on page 948.

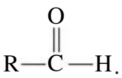
Adenosine diphosphate (ADP) and **adenosine triphosphate (ATP)** are agents involved in energy transfers during metabolism. The hydrolysis of ATP produces ADP, the ion $HPO_4{}^{2-}$, and a release of energy.

Adhesive forces are intermolecular forces between unlike molecules, such as molecules of a liquid and of a surface with which it is in contact.

ADP (See **adenosine diphosphate**.)

Alcohols contain the functional group $-OH$ and have the general formula ROH.

Aldehydes have the general formula



$$R-\overset{\overset{\displaystyle O}{\|}}{C}-H.$$

Alicyclic hydrocarbon molecules have their carbon atom skeletons arranged in rings and resemble aliphatic (rather than aromatic) hydrocarbons.

Aliphatic hydrocarbon molecules have their carbon atom skeletons arranged in straight or branched chains.

Alkali metals is the family name for the group 1 elements of the periodic table.

Alkaline earth metals is the family name for the group 2 elements of the periodic table.

Alkane hydrocarbon molecules have only single covalent bonds between carbon atoms. In their chain structures alkanes have the general formula C_nH_{2n+2}.

Alkene hydrocarbons have one or more carbon-to-carbon double bonds in their molecules. The simple alkenes have the general formula C_nH_{2n}.

Alkyl groups are alkane hydrocarbon molecules from which one hydrogen atom has been extracted. For example, the group $-CH_3$ is the **methyl** group; $-CH_2CH_3$ is the **ethyl** group.

Alkyne hydrocarbons have one or more carbon-to-carbon triple bonds in their molecules. The simple alkynes have the general formula C_nH_{2n-2}.

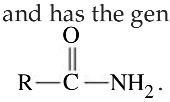
An **alloy** is a mixture of two or more metals. Some alloys are solid solutions, some are heterogeneous mixtures, and some are intermetallic compounds.

An **alpha (α) particle** is a combination of two protons and two neutrons identical to the helium ion, that is, ${}^4He^{2+}$. Alpha particles are emitted in some radioactive decay processes.

Alums are sulfates of the general formula, $M(I)M(III)(SO_4)_2 \cdot 12\,H_2O$. M(I) is most commonly an alkali metal or ammonium ion, and M(III) is most commonly Al^{3+}, Fe^{3+}, or Cr^{3+}.

Amalgams are metal alloys containing mercury. Depending on their compositions, some are liquid and some are solid.

An **amide** is derived from the ammonium salt of a carboxylic acid and has the general formula



$$R-\overset{\overset{\displaystyle O}{\|}}{C}-NH_2.$$

An **amine** is an organic base having the formula RNH_2 (primary), R_2NH (secondary), or R_3N (tertiary), depending on the number of hydrogen atoms of an NH_3 molecule that are replaced by R groups.

An **α-amino acid** is a carboxylic acid that has an amino group ($-NH_2$) attached to the carbon atom adjacent to the **carboxyl group** ($-COOH$).

Amplitude is the height of the crest of a wave above the center line of the wave.

Amphiprotic substances can act either as an acid or as a base.

Amphoteric is the term used to describe the ability of certain oxides and hydroxo compounds to act as either acids or bases.

An **angular wave function,** $Y(\theta, \phi)$, is the part of a wave function that depends on the angles θ and ϕ when the Schrüdinger wave equation is expressed in spherical polar coordinates. (See also **radial wave function**.)

Anhydride is a term meaning "without water." An acid anhydride is an element oxide that reacts with water to form an acid, and a base anhydride, to form a base.

An **anion** is a negatively charged ion. An anion migrates toward the anode in an electrochemical cell.

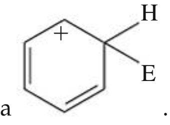
The **anode** is the electrode in an electrochemical cell at which an oxidation half-reaction occurs.

In the **anti** conformation, the methyl groups are diagonally opposite each other.

An **antibonding molecular orbital** describes regions in a molecule in which there is a low electron probability or charge density between two bonded atoms.

An **aprotic solvent** is a solvent whose molecules do not have a hydrogen atom bonded to an electronegative element.

An **arenium ion** is a cationic species with structural formula



. An arenium ion is formed when an electrophile (E^+) accepts an electron pair from the π system of the benzene ring.

Aromatic hydrocarbons are organic substances whose carbon atom skeletons are arranged in hexagonal rings, based on benzene, C_6H_6.

Asymmetric is the term used to describe a C atom with four different substituent groups. A molecule with such a C atom is chiral.

One **atmosphere** (atm) is the pressure exerted by a column of mercury exactly 760 mm high when the density of mercury is 13.5951 g/cm^3 and the acceleration due to gravity is $g = 9.80665\ m/s^2$.

The **atom** is the basic building block of matter. The number of different atoms currently known is 114. A chemical element consists of a single type of atom, and a chemical compound consists of two or more different kinds of atoms.

The **atomic mass (weight)** of an element is the average of the isotopic masses weighted according to the naturally occurring abundances of the isotopes of the element and relative to the value of exactly 12 u for a carbon-12 atom.

An **atomic mass unit**, **u**, is used to express the masses of individual atoms. One u is 1/12 the mass of a carbon-12 atom.

The **atomic number**, **Z**, is the number of protons in the nucleus of an atom. It is also the number of electrons outside the nucleus of an electrically neutral atom.

Atomic (line) spectra are produced by dispersing light emitted by excited gaseous atoms. Only a discrete set of wavelength components (seen as colored lines) is present in a line spectrum.

ATP (See **adenosine triphosphate**.)

The **aufbau process** is a method of writing electron configurations. Each element is described as differing from the preceding one in terms of the orbital to which the one additional electron is assigned.

An **average bond energy** is the average of bond-dissociation energies for a number of different species containing a particular covalent bond. (See also **bond dissociation energy**.)

The **Avogadro constant,** N_A, has a value of $6.02214 \times 10^{23}\ mol^{-1}$. It is the number of elementary units in one mole.

Avogadro's law (hypothesis) states that at a fixed temperature and pressure, the volume of a gas is directly proportional to the amount of gas and that equal volumes of different gases, compared under identical conditions of temperature and pressure, contain equal numbers of molecules.

An **azeotrope** is a solution that boils at a constant temperature, producing vapor of the same composition as the liquid. In some cases, the azeotrope boils at a lower temperature than the solution components, in other cases, at a higher temperature.

A **balanced equation** has the same number of atoms of each type on both sides. (See also **chemical equation**.)

Band theory is a form of molecular orbital theory to describe bonding in metals and semiconductors.

One **bar** is equal to 100 kilopascals (1 bar = 100 kPa).

A **barometer** is a device used to measure the pressure of the atmosphere.

Barometric pressure is the prevailing pressure of the atmosphere as indicated by a barometer.

A **base** is (1) a compound that produces hydroxide ions, OH^-, in water solution (Arrhenius theory); (2) a proton acceptor (Brønsted–Lowry theory); (3) an atom, ion, or molecule that can donate a pair of electrons to form a covalent bond (Lewis theory).

A **base ionization constant,** K_b, is the equilibrium constant for the ionization reaction of a weak base.

Basicity is a measure of the tendency of an electron pair donor to react with a proton.

The **basic oxygen process** is the principal process used to convert impure iron (pig iron) into steel.

A **battery** is a voltaic cell [or a group of voltaic cells connected in series (+ to −)] used to produce electricity from chemical change.

bcc (See **body-centered cubic**.)

A **benzyl** group is a methyl group with one hydrogen atom replaced by a phenyl group.

A **beta (β^-) particle** is an electron emitted as a result of the conversion of a neutron to a proton in certain atomic nuclei undergoing radioactive decay.

A **bidentate** ligand attaches itself to the central atom of a complex at two points in the coordination sphere.

A **bimolecular process** is an elementary process involving the collision of two molecules.

Binary compounds are compounds composed of *two* elements.

A **body-centered cubic (bcc)** crystal structure is one in which the unit cell has structural units at each corner and one in the center of the cube.

Boiling is a process in which vaporization occurs throughout a liquid. It occurs when the vapor pressure of a liquid is equal to barometric pressure.

A **bomb calorimeter** is a device used to measure the heat of a combustion reaction. The quantity measured is the heat of reaction at constant volume, $q_V = \Delta U$.

A **bond angle** is the angle between two covalent bonds. It is the angle between hypothetical lines joining the nuclei of two atoms to the nucleus of a third atom to which they are covalently bonded.

Bond-dissociation energy, D, is the quantity of energy required to break one mole of covalent bonds in a gaseous species, usually expressed in kJ mol^{-1}. (See also **average bond energy**.)

Bond length (bond distance) is the distance between the centers of two atoms joined by a covalent bond.

Bond order is one-half the difference between the numbers of electrons in bonding and in antibonding molecular orbitals in a covalent bond. A single bond has a bond order of 1; a double bond, 2; and a triple bond, 3.

A **bond pair** is a pair of electrons involved in covalent bond formation.

A **bonding molecular orbital** describes regions of high electron probability or charge density in the internuclear region between two bonded atoms.

Boyle's law states that the volume of a fixed amount of gas at a constant temperature is inversely proportional to the gas pressure.

In a **bridged halonium ion**, a halogen atom (X) is bonded to (bridges) two carbon atoms that are bonded to each other: . The halogen atom has a complete octet, comprising two bonding pairs and two lone pairs, and it bears a formal charge of 1$^+$. If the halogen atom is chlorine or bromine, the ion is called a chloronium or bromonium ion.

Buffer capacity refers to the amount of acid and/or base that a buffer solution can neutralize while maintaining an essentially constant pH.

Buffer range is the range of pH values over which a buffer solution can maintain a fairly constant pH.

A **buffer solution** resists a change in its pH. It contains components capable of neutralizing small added amounts of acids and base.

By-products are substances produced along with the principal product in a chemical process, either through the main reaction or a side reaction.

Calcination refers to the decomposition of a solid by heating at temperatures below its melting point, such as the decomposition of calcium carbonate to calcium oxide and $CO_2(g)$.

The **calorie (cal)** is the quantity of heat required to change the temperature of one gram of water by one degree Celsius.

A **calorimeter** is a device (of which there are numerous types) used to measure a quantity of heat.

A **carbohydrate** is a polyhydroxy aldehyde, a polyhydroxy ketone, a derivative of these, or a substance that yields them upon hydrolysis. Carbohydrates can be viewed as "hydrates" of carbon, in the sense that their general formulas are $C_x(H_2O)_y$.

Carbon black is a finely divided amorphous form of carbon prepared by the incomplete combustion of hydrocarbons.

The carbonyl group is found in aldehydes, ketones, and carboxylic acids .

The **carboxyl group** is 
$$\mathrm{-\overset{\overset{\displaystyle O}{\|}}{C}-OH}$$

.

A **carboxylic acid** has one or more carboxyl groups attached to a hydrocarbon chain or ring structure.

A **catalyst** provides an alternative mechanism of lower activation energy for a chemical reaction. The reaction is speeded up, and the catalyst is regenerated.

The **cathode** is the electrode of an electrochemical cell where a reduction half-reaction occurs.

Cathode rays are negatively charged particles (electrons) emitted at the negative electrode (cathode) in the passage of electricity through gases at very low pressures.

Cathodic protection is a method of corrosion control in which the metal to be protected is joined to a more active metal that corrodes instead. The protected metal acts as the cathode of a voltaic cell.

A **cation** is a positively charged ion. A cation migrates toward the cathode in an electrochemical cell.

The **cell** is the fundamental unit of living organisms.

A **cell diagram** is a symbolic representation of an electrochemical cell that indicates the substances entering into the cell reaction, electrode materials, solution concentrations, etc.

The **cell voltage (potential),** $E_{\mathbf{cell}}$, is the potential difference (voltage) between the two electrodes of an electrochemical cell.

The **Celsius** temperature scale is based on a value of 0 °C for the normal melting point of ice and 100 °C for the normal boiling point of water.

A **central atom** in a structure is an atom that is bonded to two or more other atoms.

In **chain-reaction polymerization**, a reaction is initiated by "opening up" a carbon-to-carbon double bond. Monomer units add to free-radical intermediates to produce a long-chain polymer.

The **charge density**, ρ, is the charge per unit volume in a cation.

Charles's law states that the volume of a fixed amount of gas at a constant pressure is directly proportional to the Kelvin (absolute) temperature.

A **chelate** results from the attachment of polydentate ligands to the central atom of a complex ion. Chelates are five- or six-membered rings that include the central atom and atoms of the ligands.

A **chelating agent** is a polydentate ligand. It simultaneously attaches to two or more positions in the coordination sphere of the central atom of a complex ion.

Chelation is the process of chelate formation.

The **chelation effect** refers to an exceptional stability conferred to a complex ion when polydentate ligands are present.

Chemical change (See **chemical reaction**.)

Chemical energy is the energy associated with chemical bonds and intermolecular forces.

A **chemical equation** is a symbolic representation of a chemical reaction. Symbols and formulas are used to represent reactants and products, and stoichiometric coefficients are used to balance the equation. (See also **balanced equation**.)

A **chemical formula** represents the relative numbers of atoms of each kind in a substance through symbols and numerical subscripts.

A **chemical property** is the ability (or inability) of a sample of matter to undergo a particular chemical reaction.

A **chemical reaction** is a process in which one set of substances (reactants) is transformed into a new set of substances (products).

Chemical symbols are abbreviations of the names of the elements consisting of one or two letters (e.g., N = nitrogen and Ne = neon).

Chiral refers to a molecule with a structure that is not superimposable on its mirror image. (See also **enantiomers**.)

The term ***cis*** describes geometric isomers in which two groups are attached on the same side of a double bond in an organic molecule, or along the same edge of a square in a square-planar complex, or at two adjacent vertices of an octahedral complex. (See also **geometric isomerism**.)

***cis–trans* isomerism** is a type of stereoisomerism.

A **closed system** is one that can exchange energy but not matter with its surroundings.

Cohesive forces are intermolecular forces between like molecules, such as within a drop of liquid.

Coke is a relatively pure form of carbon produced by heating coal out of contact with air (destructive distillation).

Colligative properties —vapor pressure lowering, freezing point depression, boiling point elevation, osmotic pressure—have values that depend on the number of solute particles in a solution but not on their identity.

A **colloid** is a mixture that contains particles that are larger than ions or molecules but are still submicroscopic.

The **common-ion effect** describes the effect on an equilibrium by a substance that furnishes ions that can participate in the equilibrium.

A **complementary color** is a secondary color that mixes with the opposite primary color on the color wheel to produce white light in additive color mixing or black in subtractive color mixing.

A **complex** is a polyatomic cation, anion, or neutral molecule in which groups (molecules or ions) called ligands are bonded to a central metal atom or ion.

A **complex ion** is a complex having a net electrical charge.

Composition refers to the components and their relative proportions in a sample of matter.

A **compound** is a substance made up of two or more elements. It does not change its identity in physical changes, but it can be broken down into its constituent elements by chemical changes.

Concentration (1) refers to the composition of a solution. (2) See **extractive metallurgy**.

In a **concentration cell** identical electrodes are immersed in solutions of different concentrations. The voltage (emf) of the cell is a function simply of the concentrations of the two solutions.

Condensation is the passage of molecules from the gaseous state to the liquid state.

A **condensed structural formula** is a simplified representation of a structural formula.

Conformations refer to the different spatial arrangements possible in a molecule. Examples are the "boat" and "chair" forms of cyclohexane.

A **conjugate acid** is formed when a Brønsted–Lowry base gains a proton. Every base has a conjugate acid.

A **conjugate acid–base pair** is pair of molecules or ions for which the chemical formulas differ by a single proton: H^+ (e.g., H_3O^+ and H_2O; H_2O and OH^-; NH_4^+ and NH_3; H_3PO_4 and $H_2PO_4^-$).

A **conjugate base** remains after a Brønsted–Lowry acid has lost a proton. Every acid has a conjugate base.

Consecutive reactions are two or more reactions carried out in sequence. A product of each reaction becomes a reactant in a following reaction until a final product is formed.

Constitutional isomers have different bond connectivities, and thus different skeletal structures.

The **contact process** is a process for the manufacture of sulfuric acid having as its key reaction the oxidation of $SO_2(g)$ to $SO_3(g)$ in contact with a catalyst.

Control rods are neutron-absorbing metal rods (e.g., Cd) that are used to control the neutron flux in a nuclear reactor and thereby control the rate of the fission reaction.

In a **coordinate covalent bond**, electrons shared between two atoms are contributed by just one of the atoms. As a result, the bonded atoms exhibit formal charges.

Coordination compounds are neutral complexes or compounds containing complex ions.

Coordination number is the number of positions around a central atom where ligands can be attached in the formation of a complex. Applied to a crystalline solid, coordination number signifies the number of nearest neighboring atoms (or ions of opposite charge) to any given atom (or ion) in a crystal.

Coupled reactions are sets of chemical reactions that occur together. One (or more) of the reactions taken alone is (are) *nonspontaneous* and other(s), *spontaneous*. The overall reaction is *spontaneous*.

A **covalent bond** is formed when electrons are shared between a pair of atoms. In valence bond theory, the sharing of the electrons is said to occur in the region in which atomic orbitals overlap.

Covalent radius is one-half the distance between the centers of two atoms that are bonded covalently. It is the atomic radius associated with an element in its covalent compounds.

The **critical point** refers to the temperature and pressure at which a liquid and its vapor become identical. It is the highest temperature point on the vapor pressure curve.

Crystal field theory describes bonding in complexes in terms of electrostatic attractions between ligands and the nucleus of the central metal. Particular attention is focused on the splitting of the d energy level of the central metal.

Cubic closest packed is one of the two ways in which spheres can be packed to minimize the amount of free space or voids among them.

Dalton's law of partial pressures states that in a mixture of gases, the total pressure is the sum of the partial pressures of the gases present. (See also **partial pressure**.)

The **dashed and solid wedge line notation** is a method of conveying a three-dimensional perspective to a structure plotted in a plane.

The ***d* block** refers to that section of the periodic table in which the process of orbital filling (aufbau process) involves a *d* subshell.

A **decay constant** is a first-order rate constant describing radioactive decay.

Degree of ionization refers to the extent to which molecules of a weak acid or weak base ionize. The degree of ionization increases as the weak electrolyte solution is diluted. (See also **percent ionization**.)

The **degree of unsaturation** is equal to the total number of π bonds and ring structures in a molecule.

Degenerate orbitals are orbitals that are at the same energy level.

A **delocalized molecular orbital** describes a region of high electron probability or charge density that extends over three or more atoms.

Denaturation refers to the loss of biological activity of a protein brought about by changes in its secondary and tertiary structures.

Density is a physical property obtained by dividing the mass of a material or object by its volume (i.e., mass per unit volume).

Deoxyribonucleic acid (DNA) is the substance that makes up the genes of the chromosomes in the nuclei of cells.

Deposition is the passage of molecules from the gaseous to the solid state.

Detergents are cleansing agents that act by emulsifying oils. Most common among synthetic detergents are the salts of organic sulfonic acids, $RSO_3^-Na^+$.

Dextrorotatory means the ability to rotate the plane of polarized light to the *right*, designated (+).

Diagonal relationships refer to similarities that exist between certain pairs of elements in different groups and periods of the periodic table, such as Li and Mg, Be and Al, and B and Si.

A **diamagnetic** substance has all its electrons paired and is slightly repelled by a magnetic field.

Diastereomers are optically active isomers of a compound, but their structures are *not* mirror images (as are enantiomers).

Diffraction is the dispersion of light into its different components as a result of the interference produced by the reflection of light from a grooved surface.

Diffusion refers to the spreading of a substance (usually a gas or liquid) into a region where it is not originally present as a result of random molecular motion.

A **dimer** is a molecule comprised of two simpler formula units, such as Al_2Cl_6, which is a dimer of $AlCl_3$.

Dipole moment, μ, is a measure of the extent to which a separation exists between the centers of positive and negative charge within a molecule. The unit used to measure dipole moment is the **debye**, 3.34×10^{-30} C m.

Dispersion (London) forces are intermolecular forces associated with instantaneous and induced dipoles.

In a **disproportionation reaction,** the same substance is both oxidized and reduced.

In a **double covalent bond,** *two pairs* of electrons are shared between bonded atoms. The bond is represented by a double-dash sign (=).

An **E1 reaction** is an elimination reaction in which the rate-determining step is unimolecular.

An **E2 reaction** is an elimination reaction in which the rate-determining step is bimolecular.

Effective nuclear charge, Z_{eff}, is the positive charge acting on a particular electron in an atom. Its value is the charge on the nucleus, reduced to the extent that other electrons screen the particular electron from the nucleus.

Effusion is the escape of a gas through a tiny hole in its container.

An **electrochemical cell** is a device in which the electrons transferred in an oxidation–reduction reaction are made to pass through an electrical circuit. (See also **electrolytic cell** and **voltaic cell**.)

An **electrode** is a metal surface on which an oxidation–reduction equilibrium is established between the metal and substances in solution.

Electrolysis is the decomposition of a substance, either in the molten state or in an electrolyte solution, by means of electric current.

An **electrolyte** is a substance that provides ions when dissolved in water.

An **electrolytic cell** is an electrochemical cell in which a nonspontaneous reaction is carried out by electrolysis.

Electromagnetic radiation is a form of energy propagated as mutually perpendicular electric and magnetic fields. It includes visible light, infrared, ultraviolet, X ray, and radio waves.

Electromotive force (emf) is the potential difference between two electrodes in a voltaic cell, expressed in volts.

Electron affinity (*EA*) is the energy change associated with the gain of an electron by a neutral gaseous atom.

Electron capture (EC) is a form of radioactive decay in which an electron from an inner electronic shell is absorbed by a nucleus. In the nucleus the electron is used to convert a proton to a neutron.

An **electron configuration** is a designation of how electrons are distributed among various orbitals in an atom.

Electronegativity (EN) is a measure of the electron-attracting power of a bonded atom; metals have low electronegativities, and nonmetals have high electronegativities.

The **electronegativity difference** between two atoms that are bonded together is used to assess the degree of polarity in the bond.

Electron-group geometry refers to the geometrical distribution about a central atom of the electron pairs in its valence shell.

Electron spin is a characteristic of electrons giving rise to the magnetic properties of atoms. The two possibilities for electron spin are $+\frac{1}{2}$ and $-\frac{1}{2}$.

Electrons are particles carrying the fundamental unit of negative electric charge. They are found outside the nuclei of all atoms.

Electron-withdrawing substituents are atoms or groups of atoms that draw electron density toward themselves. Highly electronegative atoms, such as F, O, N, and Cl, are examples.

An **electrophile** contains an electron-attracting region of positive charge (an electrophilic center) and is a reagent that forms a bond to its reaction partner (the nucleophile) by accepting both bonding electrons from that reaction partner.

An **electrophilic** center in a molecule is an electron-attracting region of positive charge.

In an **electrophilic substitution reaction**, an electrophile replaces another atom or group in a molecule. An example of an electrophilic substitution reaction is the replacement of an H atom in benzene with a nitro (NO_2) group.

An **electrostatic potential map** depicts the electron charge distribution in a molecule. The color red is used to represent the region with the most negative charge, and blue represents the most positive charge.

An **element** is a substance composed of a single type of atom. It cannot be broken down into simpler substances by chemical reactions.

An **elementary process** is an event that significantly alters a molecule's energy or geometry or produces a new molecule(s). It represents a single step in a reaction mechanism.

In an **elimination reaction**, atoms or groups that are bonded to adjacent atoms are eliminated as a small molecule (e.g., H_2O) and an additional bond is formed between carbon atoms.

An **empirical formula** is the simplest chemical formula that can be written for a compound, that is, having the smallest integral subscripts possible.

Enantiomers (optical isomers) are molecules whose structures are nonsuperimposable mirror images. The molecules are optically active, that is, able to rotate the plane of polarized light.

An **endothermic reaction** results in a lowering of the temperature of an isolated system or the absorption of heat by a system that interacts with its surroundings.

The **end point** is the point in a titration where the indicator used changes color. A properly chosen indicator has its end point coming as closely as possible to the equivalence point of the titration.

Energy is the capacity to do work. (See also **work**.)

An **energy-level diagram** is a representation of the allowed energy states for the electrons in atoms. The simplest energy-level diagram is that of the hydrogen atom.

The **English system** of measurement has the yard as its unit of length, the pound as its unit of mass, and the second as its unit of time.

Enthalpy, *H*, is a thermodynamic function used to describe constant-pressure processes: $H = U + PV$, and at constant pressure, $\Delta H = \Delta U + P\,\Delta V$.

Enthalpy change, Δ*H*, is the difference in enthalpy between two states of a system. For a chemical reaction carried out at constant temperature and pressure and with work limited to pressure–volume work, the enthalpy change is called the *heat o freaction at constant pressure*.

An **enthalpy diagram** is a diagrammatic representation of the enthalpy changes in a process.

Enthalpy (heat) of formation (See **standard enthalpy of formation**.)

Entropy, S, is a thermodynamic property related to the number of energy levels among which the energy of a system is spread. The greater the number of energy levels for a given total energy, the greater the entropy.

Entropy change, ΔS, is the difference in entropy between two states of a system.

An **enzyme** is a high molar mass protein that catalyzes biological reactions.

An **equation of state** is a mathematical expression relating the amount, volume, temperature, and pressure of a substance (usually applied to gases).

Equilibrium refers to a condition where forward and reverse processes proceed at equal rates and no further net change occurs. For example, amounts of reactants and products in a reversible reaction remain constant over time.

The **equilibrium constant** is the numerical value of the equilibrium constant expression.

An **equilibrium constant expression** describes the relationship among the concentrations (or partial pressures) of the substances present in a system at equilibrium.

The **equivalence point** of a titration is the condition in which the reactants are in stoichiometric proportions. They consume each other, and neither reactant is in excess.

An **ester** is the product of the elimination of H_2O from between an acid and an alcohol molecule. Esters have the general formula  $R-\overset{\overset{\displaystyle O}{\|}}{C}-O-R'$.

An **ether** has the general formula $R-O-R'$.

Eutrophication is the deterioration of a freshwater body caused by nutrients such as nitrates and phosphates, which stimulate the growth of algae, oxygen depletion, and fish kills.

Evaporation is the physical process of a liquid changing to a vapor. (See also **vaporization**.)

In an **excited state** of an atom, one or more electrons are promoted to a higher energy level than in the ground state. (See also **ground state**.)

An **exothermic reaction** produces an increase in temperature in an isolated system or, for a system that interacts with its surroundings, the evolution of heat.

Expanded valence shell is a term used to describe Lewis structures in which certain atoms in the third or higher period of the periodic table appear to require 10 or 12 electrons in their valence shells.

An **extensive property** is one, like mass or volume, whose value depends on the quantity of matter observed.

Extractive metallurgy refers to the process of extracting a metal from its ores. Generally this occurs in four steps. **Concentration** separates the ore from waste rock (gangue). **Roasting** converts the ore to the metal oxide. **Reduction** (usually with carbon) converts the oxide to the metal. **Refining** removes impurities from the metal.

The **E, Z system** is a system of nomenclature used to describe the manner in which substituent groups are attached at a carbon-to-carbon double bond.

A **face-centered cubic (fcc)** crystal structure is one in which the unit cell has structural units at the eight corners and in the center of each face of the unit cell. It is derived from the cubic closest packed arrangement of spheres.

The **Fahrenheit** temperature scale is based on a value of 32 °F as the melting point of ice and 212 °F as the boiling point of water.

A **family** of elements is a numbered group from the periodic table, sometimes carrying a distinctive name. For example, group *17* is the halogen family.

The **Faraday constant**, **F**, is the charge associated with one mole of electrons, 96,485 C/mol e^-.

Fats are triglycerides in which saturated fatty acid components predominate.

The *f* block is that portion of the periodic table where the process of filling of electron orbitals (aufbau process) involves *f* subshells. These are the lanthanide and actinide elements.

fcc (See **face-centered cubic**.)

Ferromagnetism is a property that permits certain materials (notably Fe, Co, and Ni) to be made into permanent magnets. The magnetic moments of individual atoms are aligned into domains. In the presence of a magnetic field, these domains orient themselves to produce a permanent magnetic moment.

A **Fischer projection formula** is a two-dimensional representation of a three-dimensional structural formula. It shows how the stereochemistry at a chiral carbon atom is represented in two dimensions, and how the carbon-chain backbone is arranged on the page.

The **first law of thermodynamics**, expressed as $\Delta U = q + w$, is an alternative statement of the law of conservation of energy. (See also **law of conservation of energy**.)

A **first-order reaction** is one for which the sum of the concentration-term exponents in the rate equation is 1.

Fission (See **nuclear fission**.)

A **flow battery** is a battery in which materials (reactants, products, electrolytes) pass continuously through the battery. The battery is simply a converter of chemical to electrical energy.

Formal charge is the number of outer-shell (valence) electrons in an isolated atom minus the number of electrons assigned to that atom in a Lewis structure.

The **formation constant, K_f,** describes equilibrium among a complex ion, the free metal ion, and ligands.

Formula mass is the mass of a formula unit of a compound, relative to a mass of exactly 12 u for carbon-12.

A **formula unit** is the smallest collection of atoms or ions from which the empirical formula of a compound can be established.

Fractional crystallization (recrystallization) is a method of purifying a substance by crystallizing the pure solid from a saturated solution while impurities remain in solution.

Fractional distillation (See **distillation**.)

Fractional precipitation is a technique in which two or more ions in solution, each capable of being precipitated by the same reagent, are separated by the use of that reagent.

The **Frasch process** is a method of extracting sulfur from underwater deposits. It is based on the use of superheated water to melt the sulfur.

Free radicals are highly reactive molecular fragments containing unpaired electrons.

Freezing is the conversion of a liquid to a solid that occurs at a fixed temperature known as the **freezing point**.

The **frequency** of a wave motion is the number of wave crests or troughs that pass through a given point in a unit of time. It is expressed by the unit time^{-1} (e.g., s^{-1}, also called a hertz, Hz).

A **fuel cell** is a voltaic cell in which the cell reaction is the equivalent of the combustion of a fuel. Chemical energy of the fuel is converted to electricity.

A **function of state (state function)** is a property that assumes a unique value when the state or present condition of a system is defined. This value is *independent* of how the state is attained.

A **functional group** is an atom or grouping of atoms attached to a hydrocarbon residue, R. The functional group often confers specific properties to an organic molecule.

Fusion (See **nuclear fusion**.)

Galvanic cell (See **voltaic cell**.)

Gamma (γ) rays are a form of electromagnetic radiation of high penetrating power emitted by certain radioactive nuclei.

In a **gas,** atoms or molecules are generally much more widely separated than in liquids and solids. A gas assumes the shape of its container and expands to fill the container, thus having neither definite shape nor volume.

The **gas constant, *R***, is the numerical constant appearing in the ideal gas equation ($PV = nRT$) and in several other equations as well.

In the **gauche** conformation, the methyl groups are to the left and right of each other.

In a **geminal dihalide**, a halogen adds across the double bond of an alkene, and the two halogen atoms are bonded to the same carbon.

The **general gas equation** is an expression based on the ideal gas equation and written in the form $P_1V_1/n_1T_1 = P_2V_2/n_2T_2$.

Geometric isomerism in organic compounds refers to the existence of nonequivalent structures (*cis* and *trans*) that differ in the positioning of substituent groups relative to a double bond. In complexes, the nonequivalent structures are based on the positions at which ligands are attached to the metal center.

Gibbs energy, *G*, is a thermodynamic function designed to produce a criterion for spontaneous change. It is defined through the equation $G = H - TS$.

Gibbs energy change, ΔG, is the change in Gibbs energy that accompanies a process and can be used to indicate the direction of spontaneous change. For a spontaneous process at constant temperature and pressure, $\Delta G < 0$. (See also **standard Gibbs energy change**.)

Glass is a transparent, amorphous solid consisting of Na^+ and Ca^{2+} ions in a network of SiO_4^{4-} anions. It is made by fusing together a mixture of sodium and calcium carbonates with sand.

Global warming refers to the warming of Earth that results from an accumulation in the atmosphere of gases such as CO_2 that absorb infrared radiation radiated from Earth's surface.

Graham's law states that the rates of effusion or diffusion of two different gases are inversely proportional to the square roots of their molar masses.

The **ground state** is the lowest energy state for the electrons in an atom or molecule.

A **group** is a vertical column of elements in the periodic table. Members of a group have similar properties.

A **half-cell** is a combination of an electrode and a solution. An oxidation–reduction equilibrium is established on the electrode. An electrochemical cell is a combination of two half-cells.

The **half-life** ($t_{1/2}$) of a reaction is the time required for one-half of a reactant to be consumed. In a nuclear decay process, it is the time required for one-half of the atoms present in a sample to undergo radioactive decay.

A **half-reaction** describes one portion of an overall oxidation–reduction reaction, either the oxidation or the reduction.

Halogens (group *17*) are the most reactive nonmetals, having the electron configuration ns^2np^5 in the electronic shell of highest principal quantum number.

Hard water contains dissolved minerals in significant concentrations. If the hardness is primarily due to HCO_3^- and associated cations, the water has **temporary hardness**. If the hardness is due to anions other than HCO_3^- (e.g., SO_4^{2-}), the water has **permanent hardness**.

hcp (See **hexagonal closest packed**.)

Heat is a transfer of thermal energy as a result of a temperature difference.

Heat capacity is the quantity of heat required to change the temperature of an object or substance by one degree, usually expressed as $J\,°C^{-1}$ or $cal\,°C^{-1}$. **Specific heat capacity** is the heat capacity per gram of substance, i.e., $J\,°C^{-1}\,g^{-1}$, and **molar heat capacity** is the heat capacity per mole, i.e., $J\,°C^{-1}\,mol^{-1}$.

A **heat of reaction** is energy converted from chemical to thermal (or vice versa) in a reaction. In an isolated system, this energy conversion causes a temperature change, and in a system that interacts with its surroundings, heat (q) is either evolved to or absorbed from the surroundings.

The **Heisenberg uncertainty principle** states that, when measuring the position and momentum of fundamental particles of matter, uncertainties in measurement are inevitable.

The **Henderson–Hasselbalch equation** has the form, $pH = pK_a + \log$ [conjugate base]/[acid], in which stoichiometric concentrations of the weak acid and its conjugate base are used in place of the equilibrium concentrations. There are limitations on its validity.

Henry's law relates the solubility of a gas to the gas pressure maintained above a solution of the gaseous solute. The solubility is directly proportional to the pressure of the gas above the solution.

The **hertz (Hz)** is the SI unit of frequency, equal to s^{-1}.

Hess's law states that the enthalpy change for an overall or net process is the sum of enthalpy changes for individual steps in the process.

Heterocyclic compounds are based on hydrocarbon ring structures in which one or more C atoms are replaced by atoms such as N, O, or S.

Heterogeneous catalysis is catalytic action that takes place on a surface separating two phases.

In a **heterogeneous mixture**, components separate into physically distinct regions of differing properties and often differing composition.

Hexagonal closest packed is one of the two ways in which spheres can be packed to minimize the amount of free space or voids among them. The crystal structure based on this type of packing is referred to as **hcp**.

In a **high-spin complex,** weak crystal field splitting leads to a maximum number of unpaired electrons in the *d* subshell of the central metal atom or ion.

Homogeneous catalysis refers to a catalytic reaction taking place in a single phase.

A **homogeneous mixture (solution)** is a mixture of elements and/or compounds that has a uniform composition and properties within a given sample. However, the composition and properties may vary from one sample to another.

A **homologous series** is a group of compounds that differ in composition by some constant unit ($-CH_2$ in the case of alkanes).

Hund's rule (rule of maximum multiplicity) states that whenever orbitals of equal energy are available, electrons occupy these orbitals singly before any pairing of electrons occurs.

A **hybrid orbital** is one of a set of identical orbitals reformulated from pure atomic orbitals and used to describe certain covalent bonds.

Hybridization refers to combining pure atomic orbitals to generate hybrid orbitals in the valence bond approach to covalent bonding.

A **hydrate** is a compound in which a fixed number of water molecules is associated with each formula unit, such as $CuSO_4 \cdot 5\,H_2O$.

Hydrides are compounds of hydrogen, usually divided into the categories of covalent (e.g., H_2O and HCl), ionic (e.g., LiH and CaH_2), and metallic (mostly nonstoichiometric compounds with the transition metals).

A **hydrocarbon** is a compound containing the two elements carbon and hydrogen. The C atoms are arranged in straight or branched chains or ring structures.

A **hydrogen bond** is an intermolecular force of attraction in which an H atom covalently bonded to one atom is attracted simultaneously to another highly nonmetallic atom of the same or a nearby molecule.

In a **hydrogenation reaction**, H atoms are added to multiple bonds between carbon atoms, converting carbon-to-carbon double bonds to single bonds and carbon-to-carbon triple bonds to double or single bonds. It is a reaction, for example, that converts an unsaturated to a saturated fatty acid.

Hydrolysis is a special name given to acid–base reactions in which ions act as acids or bases. As a result of hydrolysis, many salt solutions are not pH neutral, that is, $pH \neq 7$.

Hydrometallurgy refers to metallurgical procedures where water and aqueous solutions are used to extract metals from their ores. In the first step, **leaching**, the target metal is obtained in soluble form in aqueous solution. Other steps include purifying the leached solution and depositing the metal from solution.

Hydronium ion, H_3O^+, is the form in which protons are found in aqueous solution. The terms "hydrogen ion" and "hydronium ion" are often used synonymously.

The **hydroxyl** group is $—OH$ and is usually found attached to a straight or branched hydrocarbon chain (an alcohol) or a ring structure (a phenol).

A **hypothesis** is a tentative explanation of a series of observations or of a natural law.

An **ICE table** is a format for organizing the data in an equilibrium calculation. It is based on the **initial** concentrations of reactants and products, changes in concentrations to attain equilibrium, and equilibrium concentrations.

An **ideal (perfect) gas** is one whose behavior can be predicted by the ideal gas equation.

Ideal gas constant (See **gas constant**.)

The **ideal gas equation** relates the pressure, volume, temperature, and number of moles of ideal gas (n) through the expression $PV = nRT$.

An **ideal solution** has $\Delta H_{soln} = 0$ and certain properties (notably vapor pressure) that are predictable from the properties of the solution components.

An **indicator** is an added substance that changes color at the equivalence point in a titration.

The **inductive effect** refers to the shifting of electron density from one atom toward another through the chain of σ bonds that connects them.

Industrial smog is air pollution in which the chief pollutants are $SO_2(g)$, $SO_3(g)$, H_2SO_4 mist, and smoke.

Inert complex is the term used to describe a complex ion in which the exchange of ligands occurs very slowly.

The **inert pair effect** refers to the effects on the properties of certain post-transition elements that result from the presence of a pair of electrons in the s orbital of the valence shells of their atoms.

The **initial rate of a reaction** is the rate of a reaction immediately after the reactants are brought together.

An **inorganic compound** is any combination of elements that does not fit the category of organic compound. (See also **organic compound**.)

An **instantaneous rate of reaction** is the exact rate of a reaction at some precise point in the reaction. It is obtained from the slope of a tangent line to a concentration–time graph.

An **integrated rate law (equation)** is derived from a rate law (equation) by the calculus technique of integration. It relates the concentration of a reactant (or product) to elapsed time from the start of a reaction. The equation has different forms depending on the order of the reaction.

An **intensive property** is *independent* of the quantity of matter involved in the observation. Density and temperature are examples of intensive properties.

An **interhalogen** compound is a covalent compound between two or more halogen elements, such as ICl and BrF_3.

An **intermediate** is the product of one reaction that is consumed in a following reaction in a process that proceeds through several steps.

The **internal energy, U**, of a system is the total energy attributed to the particles of matter and their interactions within a system.

An **ion** is a charged species consisting of a single atom or a group of atoms. It is formed when a neutral atom or a covalently bonded group of atoms either gains or loses electrons.

Ion exchange is a process in which ions held to the surface of an ion exchange material are exchanged for other ions in solution. For example, Na^+ may be exchanged for Ca^{2+} and Mg^{2+}, or OH^- may be exchanged for SO_4^{2-}.

An **ion pair** is an association of a cation and an anion in solution. Such combinations, when they occur, can have a significant effect on solution equilibria.

An **ion product, Q_{sp}**, is formulated in the same manner as a solubility product constant, K_{sp}, but with *nonequilibrium* concentration terms. A comparison of Q_{sp} and K_{sp} provides a criterion for precipitation from solution.

The **ion product of water, K_w**, is the product of $[H_3O^+]$ and $[OH^-]$ in pure water or in an aqueous solution. This product has a unique value that depends only on temperature. At 25 °C, $K_w = 1.0 \times 10^{-14}$.

An **ionic bond** results from the transfer of electrons between metal and nonmetal atoms. Positive and negative ions are formed and held together by electrostatic attractions.

An **ionic compound** is a compound consisting of positive and negative ions that are held together by electrostatic forces of attraction.

Ionic radius is the radius of a spherical ion. It is the atomic radius associated with an element in its ionic compounds.

The **first ionization energy, I**, is the energy required to remove the most loosely held electron from a *gaseous* atom. The second ionization energy, I_2, is the energy required to remove an electron from a gaseous unipositive ion, and so on.

An **irreversible** process takes place in one or several finite steps such that the system is not in equilibrium with its surroundings.

The **isoelectric point, pI**, of an amino acid is the pH at which the dipolar structure or **zwitterion** predominates.

Isoelectronic species have the same number of electrons (usually in the same configuration). Na^+ and Ne are isoelectronic, as are CO and N_2.

An **isolated system** is one that exchanges neither energy nor matter with its surroundings.

Isomers are two or more compounds having the same formula but different structures and therefore different properties.

Isotopes of an element are atoms with different numbers of neutrons in their nuclei. That is, isotopes of an element have the same atomic numbers but different mass numbers.

Isotopic mass (See **nuclidic mass**.)

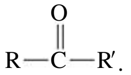
IUPAC (or **IUC**) refers to the International Union of Pure and Applied Chemistry.

K_c is the relationship among the *concentrations* of the reactants and products in a reversible reaction at equilibrium. Concentrations are expressed as molarities.

K_p, the partial pressure equilibrium constant, is the relationship that exists among the partial pressures of gaseous reactants and products in a reversible reaction at equilibrium. Partial pressures are expressed in atm.

The **Kelvin** temperature is an **absolute** temperature. That is, the lowest attainable temperature is $0\ K = -273.15\ °C$ (the temperature at which molecular motion ceases). Kelvin and Celsius temperatures are related through the expression $T\,(K) = t(°C) + 273.15$.

A **ketone** has the general formula



$$R-\overset{\overset{O}{\|}}{C}-R'.$$

A **kilopascal (kPa)** is a unit of pressure equal to 1000 pascals (Pa) or $1000\ N/m^{-2}$. The standard atmosphere of pressure is 101.325 kPa.

Kinetic energy is energy of motion. The kinetic energy of an object with mass m and velocity u is $K.E. = \frac{1}{2}mu^2$.

The **kinetic-molecular theory of gases** is a model for describing gas behavior. It is based on a set of assumptions and yields equations from which various properties of gases can be deduced.

Labile complex is the term used to describe a complex ion in which a rapid exchange of ligands occurs.

The **lanthanide contraction** refers to the decrease in atomic size in a series of elements in which an f subshell fills with electrons (an inner transition series). It results from the ineffectiveness of f electrons in shielding outer-shell electrons from the nuclear charge of an atom.

The **lanthanides** are the elements $(Z = 58 - 71)$ characterized by a partially filled $4f$ subshell in their atoms. Because lanthanum resembles them, La $(Z = 57)$ is generally considered together with them.

Lattice energy is the quantity of energy released in the formation of one mole of a crystalline ionic solid from its separated gaseous ions.

Gay-Lussac's law of combining volumes states that, when compared at the same temperature and pressure, the volumes of *gases* involved in a reaction are in the ratio of small whole numbers.

The **law of conservation of energy** states that energy can neither be created nor destroyed in ordinary processes.

The **law of conservation of mass** states that the total mass of the products of a chemical reaction is the same as the total mass of the reactants entering into the reaction.

The **law of constant composition (definite proportions)** states that all samples of a compound have the same composition, that is, the same proportions by mass of the constituent elements.

The **law of multiple proportions** states that if two elements form two or more compounds, the masses of one element combined with a fixed mass of the second are in the ratio of small whole numbers when the different compounds are compared.

The **leaving group** is the species expelled from an electrophilic molecule following attack by a nucleophile.

Le Châtelier's principle states that an action that tends to change the temperature, pressure, or concentrations of reactants in a system at equilibrium stimulates a response that partially offsets the change while a new equilibrium condition is established.

Levorotatory means the ability to rotate the plane of polarized light to the *left*, designated (−).

Lewis acid (See **acid**.)

Lewis base (See **base**.)

A **Lewis structure** is a combination of Lewis symbols that depicts the transfer or sharing of electrons in a chemical bond.

In the **Lewis symbol** of an element, valence electrons are represented by dots placed around the chemical symbol of the element.

The **Lewis theory** refers to a description of chemical bonding through Lewis symbols and Lewis structures in accordance with a particular set of rules.

Ligands are the groups that are coordinated (bonded) to the central atom in a complex.

The **limiting reactant (reagent)** in a reaction is the reactant that is consumed completely. The quantity of product(s) formed depends on the quantity of the limiting reactant.

Line-angle formulas are shorthand representations of organic molecules in which bond lines are drawn, but chemical symbols are written only for elements other than carbon and hydrogen.

A **line spectrum** is produced from the emission of light produced from excited atom or ions. The spectrum contains lines at discrete wavelengths which arise from the transition of an electron from one energy level to another.

Lipids include a variety of naturally occurring substances (e.g., fats and oils) sharing the property of solubility in solvents of low polarity [such as in $CHCl_3$, CCl_4, C_6H_6, and $(C_2H_5)_2O$].

In a **liquid**, atoms or molecules are in close proximity (although generally not as close as in a solid). A liquid occupies a definite volume, but has the ability to flow and assume the shape of its container.

London forces (See **dispersion forces**.)

A **lone pair** is a pair of electrons found in the valence shell of an atom and *not* involved in bond formation.

In a **low-spin complex**, strong crystal field splitting leads to a minimum number of unpaired electrons in the d subshell of the central metal atom or ion.

Magic numbers is a term used to describe numbers of protons and neutrons that confer a special stability to an atomic nucleus.

The **main-group elements** are those in which s or p subshells are being filled in the aufbau process. They are also referred to as the s-block and p-block elements. They are found in groups 1, 2, and 13–18 in the periodic table (the A groups).

A **manometer** is a device used to measure the pressure of a gas, usually by comparing the gas pressure with barometric pressure.

Mass describes the quantity of matter in an object.

The **mass number, *A*,** is the total of the number of protons and neutrons in the nucleus of an atom.

A **mass spectrometer (mass spectrograph)** is a device used to separate and to measure the quantities and masses of different ions in a beam of positively charged gaseous ions.

Matter is anything that occupies space, has the property known as mass, and displays inertia.

Melting is the transition of a solid to a liquid and occurs at the **melting point**. The melting point and freezing point of a substance are identical.

A **meta (*m*-) isomer** has two substituents on a benzene ring separated by one C atom.

Metabolism refers to the totality of the chemical reactions occurring in living organisms.

A **metal** is an element whose atoms have small numbers of electrons in the outermost electronic shell. Removal of an electron(s) from a metal atom occurs without great difficulty, producing a positive ion (cation). Metals generally have a lustrous appearance, are malleable and ductile, and are able to conduct heat and electricity.

Metal carbonyls are complexes with d-block metals as central atoms and CO molecules as ligands, e.g., $Ni(CO)_4$.

Metallic radius is one-half the distance between the centers of adjacent atoms in a solid metal.

A **metalloid** is an element that may display both metallic and nonmetallic properties under the appropriate conditions.

A **millimeter of mercury (mmHg)** is a unit of pressure, usually applied to gases. For example, standard atmospheric pressure is equal to the pressure exerted by a 760-mm column of mercury.

A **millimole (mmol)** is one-thousandth of a mole (0.001 mol). It is especially useful in titration calculations.

A **mixture** is any sample of matter that is not pure, that is, not an element or compound. The composition of a mixture, unlike that of a substance, can be varied. Mixtures are either *homogeneous* or *heterogeneous*.

Moderator control slows down energetic neutrons from a fission process so that they are able to induce additional fission.

Molality, m, is a solution concentration expressed as the amount of solute, in moles, divided by the mass of solvent, in kg.

Molar mass, M, is the mass of one mole of atoms, formula units, or molecules of a substance.

A **mole** is an amount of substance containing Avogadro's number (6.02214×10^{23}) of atoms, formula units, or molecules.

Mole fraction describes a mixture in terms of the fraction of all the molecules that are of a particular type. It is the amount of one component, in moles, divided by the total amount of all the substances in the mixture.

A **mole percent** is a mole fraction expressed on a percentage basis, that is, mole fraction × 100%.

A **molecular compound** is a compound comprised of discrete molecules.

A **molecular formula** denotes the numbers of the different atoms present in a molecule. In some cases the molecular formula is the same as the empirical formula; in others it is an integral multiple of that formula.

Molecular geometry refers to the geometric shape of a molecule or polyatomic ion. In a species in which all electron pairs are bond pairs, the molecular geometry is the same as the electron-group geometry. In other cases, the two properties are related but not the same.

Molecular mass is the mass of a molecule relative to a mass of exactly 12 u for carbon-12.

Molecular orbital theory describes the covalent bonds in a molecule by replacing atomic orbitals of the component atoms by molecular orbitals belonging to the molecule as a whole. A set of rules is used to assign electrons to these molecular orbitals, thereby yielding the electronic structure of the molecule.

A **molecule** is a group of bonded atoms held together by covalent bonds and existing as a separate entity. A molecule is the smallest entity having the characteristic proportions of the constituent atoms present in a substance.

A **monodentate ligand** is a ligand that is able to attach to a metal center in a complex at only one position and using just one lone pair of electrons.

A **monosaccharide** is a single, simple molecule having the structural features of a carbohydrate. It can also be called a simple sugar.

A **multiple covalent bond** is a bond in which more than two electrons are shared between the bonded atoms.

A **natural law** is a concise statement, often in mathematical terms, that summarizes observations of certain natural phenomena.

The **Nernst equation** is used to relate E_{cell}, E°_{cell} and the activites of the reactants and products in a cell reaction.

A **net ionic equation** represents a reaction between ions in solution in such a way that all nonparticipant (spectator) ions are eliminated from the equation. The equation must be balanced both atomically and for net electric charge.

A **network covalent solid** is a substance in which covalent bonds extend throughout the crystal, making the covalent bond both an *intra*molecular and an *inter*molecular force.

In a **neutralization reaction**, an acid and a base react in stoichiometric proportions, so that there is no excess of either acid or base in the final solution. The products are water and a salt.

Neutrons are electrically neutral fundamental particles of matter found in all atomic nuclei except that of the simple hydrogen atom, protium, ${}^{1}\text{H}$.

The **neutron number** is the number of neutrons in the nucleus of an atom. It is equal to the mass number (A) minus the atomic number (Z).

Noble gases are elements whose atoms have the electron configuration ns^2np^6 in the electronic shell of highest principal quantum number. (The noble gas helium has the configuration $1s^2$.)

A **nonelectrolyte** is a substance that is essentially non-ionized, both in the pure state and in solution.

A **nonmetal** is an element whose atoms tend to gain small numbers of electrons to form negative ions (anions) with the electron configuration of a noble gas. Nonmetal atoms may also alter their electron configurations by sharing electrons. Nonmetals are mostly gases, liquid (bromine), or low melting point solids and are very poor conductors of heat and electricity.

A **nonspontaneous process** is one that will not occur naturally. A nonspontaneous process can be brought about only by intervention from outside the system, as in the use of electricity to decompose a chemical compound (electrolysis).

The **normal boiling point** is the temperature at which the vapor pressure of a liquid is 1 atm. It is the temperature at which the liquid boils in a container open to the atmosphere at a pressure of 1 atm.

A **nuclear equation** represents the changes that occur during a nuclear process. The target nucleus and bombarding particle are represented on the left side of the equation, and the product nucleus and ejected particle on the right side.

Nuclear fission is a radioactive decay process in which a heavy nucleus breaks up into two lighter nuclei and several neutrons, accompanied by the release of energy.

In **nuclear fusion** small atomic nuclei are fused into larger ones, with some of their mass being converted to energy.

Nucleic acids are cell components comprised of purine and pyrimidine bases, pentose sugars, and phosphoric acid.

A **nucleophile** is a reactant that seeks out a center of positive charge as a point of attack in a chemical reaction.

A **nucleophilic substitution reaction** is a reaction between a nucleophile and an electrophile. The nucleophile attacks at a positive center on the electrophile, and the leaving group is ejected from another point.

Nucleophilicity is a measure of how readily (how fast) a nucleophile attacks an electrophilic carbon atom bearing a leaving group.

Nuclide is a term used to designate an atom with a specific atomic number and mass number. It is represented by the symbolism ${}^{A}_{Z}\text{E}$.

An **octet** refers to *eight* electrons in the outermost (valence) electronic shell of an atom in a Lewis structure.

The **octet rule** states that the number of electrons associated with bond pairs and lone pairs of electrons for each of the Lewis symbols (except H) in a Lewis structure will be eight (an **octet**).

Oils are triglycerides in which unsaturated fatty acid components predominate.

Olefins are organic compounds that contain one or more carbon-to-carbon double bonds.

Oligosaccharides are carbohydrates consisting of two to ten monosaccharide units. (See also **sugar**.)

An **open system** is one that can exchange both matter and energy with its surroundings.

Optical isomerism results from the presence of a chiral atom in a structure, leading to a pair of optical isomers that differ only in the direction that they rotate the plane of polarized light. (See also **enantiomers**.)

Optical isomers, also called enantiomers (nonsuperimposable mirror images), are isomers that differ only in the direction they rotate the plane of polarized light.

An **orbital** is a mathematical function used to describe regions in an atom where the electron charge density or the probability of finding an electron is high. The several kinds of orbitals ($s, p, d, f, \ldots$) differ from one another in the shapes of the regions of high electron charge density they describe.

An **orbital diagram** is a representation of an electron configuration in which the most probable orbital designation and spin of each electron in the atom are indicated.

The **order of a reaction** relates to the exponents of the concentration terms in the rate law for a chemical reaction. The order can be stated with respect to a particular reactant (first order in A, second order in B, . . .) or, more commonly, as the overall order. The overall order is the sum of the concentration-term exponents.

An **organic compound** is made up of carbon and hydrogen or carbon, hydrogen and a small number of other elements, such as oxygen, nitrogen, and sulfur.

An **ortho (*o*-) isomer** has two substituents attached to adjacent C atoms in a benzene ring.

Osmosis is the net flow of solvent molecules through a semipermeable membrane, from a more dilute solution (or from the pure solvent) into a more concentrated solution.

Osmotic pressure is the pressure that would have to be applied to a solution to stop the passage through a semipermeable membrane of solvent molecules from the pure solvent.

An **overall reaction** or **overall equation** is the overall or net change that occurs when a process is carried out in more than one step.

An **overpotential** is the voltage in excess of the theoretical value required to produce a particular electrode reaction in electrolysis.

Oxidation is a process in which electrons are "lost" and the oxidation state of some atom increases. (Oxidation can occur only in combination with reduction.)

In an **oxidation–reduction (redox)** reaction certain atoms undergo changes in oxidation state. The substance containing atoms whose oxidation states *increase* is **oxidized**. The substance containing atoms whose oxidation states *decrease* is **reduced**.

An **oxidation state** relates to the number of electrons an atom loses, gains, or shares in combining with other atoms to form molecules or polyatomic ions.

An **oxidizing agent (oxidant)** makes possible an oxidation process by itself being *reduced*.

An **oxoacid** is an acid in which an ionizable hydrogen atom(s) is bonded through an oxygen atom to a central atom, that is, $\text{E}{-}\text{O}{-}\text{H}$. Other groups bonded to the central atom are either additional $-\text{OH}$ groups or O atoms (or in a few cases H atoms).

An **oxoanion** is a polyatomic anion containing a nonmetal, such as Cl, N, P, or S, in combination with some number of oxygen atoms.

Pairing energy is the energy requirement to force an electron into an orbital that is already occupied by one electron.

A **para (*p*-) isomer** has two substituents located opposite to one another on a benzene ring.

A **paramagnetic** substance has one or more unpaired electrons in its atoms or molecules. It is attracted into a magnetic field.

A **partial pressure** is the pressure exerted by an individual gas in a mixture, independently of other gases. Each gas in the mixture expands to fill the container and exerts its own partial pressure.

A **pascal (pa)** is a pressure of one N/m^2.

The **Pauli exclusion principle** states that no two electrons may have all four quantum numbers alike. This limits occupancy of an orbital to two electrons with opposing spins.

The ***p* block** is that portion of the periodic table in which the filling of electron orbitals (aufbau process) involves *p* subshells.

A **peptide bond** is formed by the elimination of a water molecule from between two amino acid molecules. The H atom comes from the $-\text{NH}_2$ group of one amino acid and the $-\text{OH}$ group, from the $-\text{COOH}$ group of the other acid.

The **percent ionization** of a weak acid or a weak base is the percent of its molecules that ionize in an aqueous solution.

Percent natural abundances refer to the relative proportions, expressed as percentages by number, in which the isotopes of an element are found in natural sources.

Percent yield is the percent of the theoretical yield of product that is actually obtained in a chemical reaction. (See also **actual yield** and **theoretical yield**.)

A **perfect gas** is one whose behavior can be predicted by the ideal gas equation. It is also used to describe a gas whose molecules are "point masses" that do not interact with one another. (See also **ideal gas**.)

A **period** is a horizontal row of the periodic table. All members of a period have atoms with the same highest principal quantum number.

The **periodic law** refers to the periodic recurrence of certain physical and chemical properties when the elements are considered in terms of increasing atomic number.

The **periodic table** is an arrangement of the elements, by atomic number, in which elements with similar physical and chemical properties are grouped together in vertical columns.

Permanent hard water (See **hard water**.)

The **peroxide** ion has the structure

.

pH is a shorthand designation for $[\text{H}_3\text{O}^+]$ in a solution. It is defined as $\text{pH} = -\log[\text{H}_3\text{O}^+]$.

A **phase diagram** is a graphical representation of the conditions of temperature and pressure at which solids, liquids, and gases (vapors) exist, either as single phases or states of matter or as two or more phases in equilibrium.

A **phenol** has the functional group $-\text{OH}$ as part of an aromatic hydrocarbon structure.

A **phenyl group** is a benzene ring from which one H atom has been removed: $-\text{C}_6\text{H}_5$.

The **photoelectric effect** is the emission of electrons by certain materials when their surfaces are struck by electromagnetic radiation of the appropriate frequency.

A **photon** is a "particle" of light. The energy of a beam of light is concentrated into these photons.

In a **physical change**, one or more physical properties of a sample of matter change, but the composition remains unchanged.

A **physical property** is a characteristic that a substance can display without undergoing a change in its composition.

A **pi (π) bond** results from the side-to-side overlap of *p* orbitals, producing a high electron charge density above and below the line joining the bonded atoms.

Pig iron is an impure form of iron (about 95% Fe and 3–4% C, together with small quantities of Mn, Si, and P) produced in a blast furnace.

p*K* is a shorthand designation for an ionization constant: $pK = -\log K$. p*K* values are useful when comparing the relative strengths of acids or bases.

Planck's constant, *h*, is the proportionality constant that relates the energy of a photon of light to its frequency. Its value is 6.626×10^{-34} J s.

Plaster of Paris, $CaSO_4 \cdot \frac{1}{2}H_2O$, is a hemihydrate of calcium sulfate obtained by heating gypsum, $CaSO_4 \cdot 2\,H_2O$. It is a widely used material in the construction industry.

pOH is a shorthand designation for $[OH^-]$ in a solution: $pOH = -\log[OH^-]$.

In a **polar covalent bond** a separation exists between the centers of positive and negative charge in the bond.

In a **polar molecule,** the presence of one or more polar covalent bonds leads to a separation of the positive and negative charge centers for the molecule as a whole. A polar molecule has a resultant dipole moment.

Polarizability describes the ease with which the electron cloud in an atom or molecule can be distorted in an electric field, that is, the ease with which a dipole can be induced.

A **polyatomic ion** is a combination of two or more covalently bonded atoms that exists as an ion.

A **polydentate ligand** is capable of donating more than a single electron pair to the metal center of a complex, from different atoms in the ligand and to different sites in the geometric structure.

In a **polyhalide ion** two or more halogen atoms are covalently bonded into a polyatomic anion, e.g., I_3^-.

Polymorphism refers to the existence of a solid substance in more than one crystalline form.

In a **polypeptide**, a large number of amino acid units join together through peptide bonds.

A **polyprotic acid** is capable of losing more than a single proton per molecule in acid–base reactions. Protons are lost in a stepwise fashion, with the first proton being the most readily lost.

A **polysaccharide** is a carbohydrate (such as starch or cellulose) consisting of more than ten monosaccharide units.

Positional isomers differ in the position on a hydrocarbon chain or ring where a functional group(s) is attached.

A **positron (β^+)** is a *positive* electron emitted as a result of the conversion of a proton to a neutron in a radioactive nucleus.

Potential energy is energy due to position or arrangement. It is the energy associated with forces of attraction and repulsion between objects.

The term **ppb** (parts per billion) refers to the number of parts of a component to one billion parts of the medium in which it is found.

The term **ppm** (parts per million) refers to the number of parts of a component to one million parts of the medium in which it is found.

The term **ppt** (parts per trillion) refers to the number of parts of a component to one trillion parts of the medium in which it is found.

A **precipitate** is an insoluble solid that deposits from a solution as a result of a chemical reaction.

Precision is the degree of reproducibility of a measured quantity—the closeness of agreement among repeated measurements.

Pressure is a force per unit area. Applied to gases, pressure is most easily understood in terms of the height of a liquid column that can be maintained by the gas.

Pressure–volume work is work associated with the expansion or compression of gases.

A **primary carbon** is attached to one other carbon atom.

A **primary battery** produces electricity from a chemical reaction that cannot be reversed. As a result the battery cannot be recharged.

A **primary color** is one of a set of colors that when added together as light produce white light. Subtractive mixing leads to an absence of color (black). Red, yellow, and blue are a set of primary colors.

Hydrogen atoms attached to a primary carbon atom are called **primary hydrogen atoms**.

Primary structure refers to the sequence of amino acids in the polypeptide chains that make up a protein.

A **principal electronic shell (level)** refers to the collection of all orbitals having the same value of the principal quantum number, *n*. For example, the 3*s*, 3*p*, and 3*d* orbitals comprise the third principal shell ($n = 3$).

The **products** are the substances formed in a chemical reaction.

Properties are qualities or attributes that can be used to distinguish one sample of matter from others.

A **protein** is a large polypeptide, that is, having a molecular mass of 10,000 u or more.

In a **protic solvent** the molecules have hydrogen atoms bonded to electronegative atoms, such as oxygen or nitrogen.

A **proton acceptor** is a base in the Brønsted–Lowry acid–base theory.

A **proton donor** is an acid in the Brønsted–Lowry acid–base theory.

Proton number (See **atomic number**.)

Protons are fundamental particles carrying the basic unit of positive electric charge and found in the nuclei of all atoms.

Pyrometallurgy is the traditional approach to extractive metallurgy that uses dry solid materials heated to high temperatures. (See also **extractive metallurgy** and **hydrometallurgy**.)

Qualitative cation analysis is a laboratory method, based on a variety of solution equilibrium concepts, for determining the presence or absence of certain cations in a sample.

A **quantum** refers to a discrete unit of energy that is the smallest quantity by which the energy of a system can change.

Quantum numbers are integral numbers whose values must be specified in order to solve the equations of wave mechanics. Three different quantum numbers are required: the *principal quantum number, n*; the *orbital angular momentum quantum number, l*; and the *magnetic quantum number,* m_l. The permitted values of these numbers are interrelated.

A **quaternary carbon** is attached to four carbon atoms.

Quaternary structure is the highest order structure that is found in some proteins. It describes how separate polypeptide chains may be assembled into a larger, more complex structure.

Quicklime is a common name for calcium oxide, CaO.

A **racemic mixture** is a mixture containing equal amounts of the enantiomers of an optically active substance.

A **rad** is a quantity of radiation able to deposit 1×10^{-2} J of energy per kilogram of matter.

A **radial wave function,** $R(r)$, is the part of a wave function that depends only on the distance r when the Schrödinger wave equation is expressed in spherical polar coordinates. (See also **angular wave function**.)

Radical (See **free radical**.)

The **radioactive decay law** states that the rate of decay of a radioactive material—the activity, A—is directly proportional to the number of atoms present.

A **radioactive decay series** is a succession of individual steps whereby an initial radioactive isotope (e.g., ^{238}U) is ultimately converted to a stable isotope (e.g., ^{206}Pb).

Radioactivity is a phenomenon in which small particles of matter (α or β particles) and/or electromagnetic radiation (γ rays) are emitted by unstable atomic nuclei.

A **random error** is an error made by the experimenter in performing an experimental technique or measurement, such as the error in estimating a temperature reading on a thermometer.

Raoult's law states that the vapor pressure of a solution component is equal to the product of the vapor pressure of the pure liquid and its mole fraction in solution: $P_A = x_A P_A^{\circ}$.

The **rate constant,** k**,** is the proportionality constant in a rate law that permits the rate of a reaction to be related to the concentrations of the reactants.

A **rate-determining step** in a reaction mechanism is an elementary process that is instrumental in establishing the rate of the overall reaction, usually because it is the slowest step in the mechanism.

The **rate law (rate equation)** for a reaction relates the reaction rate to the concentrations of the reactants. It has the form: $\text{rate} = k[A]^m[B]^n \ldots.$

The **rate of reaction** describes how fast reactants are consumed and products are formed, usually expressed as change of concentration per unit time.

Reactants are the substances that enter into a chemical reaction. This term is often applied to *all* the substances involved in a reversible reaction, but it can also be limited to the substances that appear on the *left* side of a chemical equation—the starting substances. (Substances on the *right* side of the equation are usually called products.)

A **reaction intermediate** is a species formed in one elementary reaction in a reaction mechanism and consumed in a subsequent one. As a result, the species does not appear in the equation for the overall reaction.

A **reaction mechanism** is a set of elementary steps or processes by which a reaction is proposed to occur. The mechanism must be consistent with the stoichiometry and rate law of the overall reaction.

A **reaction profile** is a graphical representation of a chemical reaction in terms of the energies of the reactants, activated complex(es), and products.

The **reaction quotient,** Q, is a ratio of concentration terms (or partial pressures) having the same form as an equilibrium constant expression, but usually applied to *nonequilibrium* conditions.

In a **rearrangement reaction**, a molecule is converted into another of its isomeric forms.

Recrystallization (See **fractional crystallization**.)

A **reducing agent (reductant)** makes possible a reduction process by itself becoming *oxidized*.

A **reducing sugar** is one that is able to reduce $Cu^{2+}(aq)$ to red, insoluble Cu_2O. The sugar must have available an aldehyde group, which is oxidized to an acid.

A **reduction** process is one in which electrons are "gained" and the oxidation state of some atom decreases. (Reduction can only occur in combination with oxidation.) (See also **extractive metallurgy**.)

Refining (See **extractive metallurgy**.)

A **rem** is a unit of radiation related to the rad, but taking into account the varying effects on biological matter of different types of radiation of the same energy.

Representative elements (See **main-group elements**.)

Resonance occurs when two or more plausible Lewis structures can be written for a species. The true structure is a composite or *hybrid* of these different contributing structures.

Reverse osmosis is the passage through a semipermeable membrane of solvent molecules *from a solution into a pure solvent*. It can be achieved by applying to the solution a pressure in excess of its osmotic pressure.

A **reversible process** is one that can be made to reverse direction by just an infinitesimal change in a system property.

Ribonucleic acid (RNA), through its **messenger RNA (mRNA)** and **transfer RNA (tRNA)** forms, is involved in the synthesis of proteins.

Roasting (See **extractive metallurgy**.)

The **root-mean-square speed** is the square root of the average of the squares of the speeds of all the gas molecules in a gaseous sample.

The **R, S system** is used to indicate the arrangement of the four groups bonded to a chiral center and to provide names that distinguish between optical isomers.

A **salt bridge** is a device (a U-tube filled with a salt solution) used to join two half-cells in an electrochemical cell. The salt bridge permits the flow of ions between the two half-cells.

The **salt effect** is that of ions *different* from those directly involved in a solution equilibrium. The salt effect is also known as the diverse or "uncommon" ion effect.

Salts are ionic compounds in which hydrogen atoms of acids are replaced by metal ions. Salts are produced by the neutralization of acids with bases.

Saponification is the hydrolysis of a triglyceride by a strong base. The products are glycerol and a soap.

Saturated hydrocarbon molecules contain only single bonds between carbon atoms.

A **saturated solution** is one that contains the maximum quantity of solute that is normally possible at the given temperature.

The *s* **block** refers to the portion of the periodic table in which the filling of electron orbitals (aufbau process) involves the s subshell of the electronic shell of highest principal quantum number.

The **Schrödinger equation** describes the electron in a hydrogen atom as a matter wave. Solutions to the Schrödinger equation are called wave functions.

The **scientific method** refers to the general sequence of activities—observation, experimentation, and the formulation of hypotheses, laws, and theories—that lead to the advancement of scientific knowledge.

The **second law of thermodynamics** relates to the direction of spontaneous change. One statement of the law is that all spontaneous processes produce an increase in the entropy of the universe.

A **secondary battery** produces electricity from a reversible chemical reaction. When electricity is passed through the battery in the reverse direction the battery is recharged.

A **secondary carbon** is attached to two other carbon atoms.

A **secondary color** is the complement of a **primary color**. When light of a primary color and its complement (secondary) color are added, the result is white light. When they are subtracted, the result is an absence of color (black).

The **secondary structure** of a protein describes the structure or shape of a polypeptide chain, for example, a coiled helix.

A **second-order reaction** is one for which the sum of the concentration-term exponents in the rate equation is 2.

Self-ionization is an acid–base reaction in which one molecule acts as an acid and donates a proton to another molecule of the same kind acting as a base.

The **shielding effect** refers to the effect of inner-shell electrons in shielding or screening outer-shell electrons from the full effects of the nuclear charge. In effect the inner electrons partially reduce the nuclear charge. (See also **effective nuclear charge**.)

A **side reaction** is a reaction that produces an undesired or unexpected product and accompanies a reaction intended to produce something else.

A **sigma (σ) bond** results from the end-to-end overlap of simple or hybridized atomic orbitals along the straight line joining the nuclei of the bonded atoms.

Significant figures are those digits in an experimentally measured quantity that establish the precision with which the quantity is known.

A **silicone** is an organosilicon polymer containing $O—Si—O$ bonds.

Simultaneous reactions are two or more reactions that occur at the same time.

A **single covalent bond** results from the sharing of *one pair* of electrons between bonded atoms. It is represented by a single dash sign (—).

A **skeletal structure** is an arrangement of atoms in a Lewis structure to correspond to the actual arrangement found by experiment.

Slaked lime is a common name for calcium hydroxide, $Ca(OH)_2$.

Smog is the general term used to refer to a condition in which polluted air reduces visibility, causes stinging eyes and breathing difficulties, and produces additional minor and major health problems. (See also **industrial smog** and **photochemical smog**.)

S_N1 is the designation for a nucleophilic substitution reaction in which the rate-determining step is unimolecular.

S_N2 is the designation for a nucleophilic substitution reaction in which the rate-determining step is bimolecular.

Soaps are the salts of fatty acids, e.g., $RCOO^-Na^+$, where the R group is a hydrocarbon chain containing from 3 to 21 C atoms. Sodium and potassium soaps are the common soaps used as cleansing agents.

Solders are low-melting alloys used for joining wires or pieces of metal. They usually contain metals such as Sn, Pb, Bi, and Cd.

In a **solid**, atoms or molecules are in close contact, often in a highly organized arrangement. A solid has a definite shape and occupies a definite volume. (See also **crystal**.)

The **solubility** of a substance is the concentration of its saturated solution.

The **solubility product constant, K_{sp}**, is the equilibrium constant that describes the formation of a saturated solution of a slightly soluble ionic compound. It is the product of ionic concentration terms, with each term raised to an appropriate power.

A **solute** is a solution component that is dissolved in a solvent. A solution may have several solutes, with the solutes generally present in lesser amounts than is the solvent.

Solution (See **homogeneous mixture**.)

The **solvent** is the solution component in which one or more solutes are dissolved. Usually the solvent is present in greater amount than are the solutes and determines the state of matter in which the solution exists.

An ***sp* hybrid orbital** is one of the pair of orbitals formed by the hybridization of one s and one *p* orbital. The angle between the two orbitals is 180°.

An **sp^2 hybrid orbital** is one of the three orbitals formed by the hybridization of one s and two *p* orbitals. The angle between any two of the orbitals is 120°.

An **sp^3 hybrid orbital** is one of the four orbitals formed by the hybridization of one *s* and three *p* orbitals. The angle between any two of the orbitals is the tetrahedral angle—109.5°.

An **sp^3d hybrid orbital** is one of the five orbitals formed by the hybridization of one *s*, three *p*, and one *d* orbital. The five orbitals are directed to the corners of a trigonal bipyramid.

An **sp^3d^2 hybrid orbital** is one of the six orbitals formed by the hybridization of one *s*, three *p*, and two *d* orbitals. The six orbitals are directed to the corners of a regular octahedron.

***spdf* notation** is a method of describing electron configurations in which the numbers of electrons assigned to each orbital are denoted as superscripts. For example, the electron configuration of Cl is $1s^22s^22p^63s^23p^5$.

The **specific heat** of a substance is the quantity of heat required to change the temperature of one gram of the substance by one degree Celsius.

Spectator ions are ionic species that are present in a reaction mixture but do not take part in the reaction. They are usually eliminated from a chemical equation.

The **spectrochemical series** is a ranking of ligand abilities to produce a splitting of the *d* energy level of a central metal ion in a complex ion.

Speed of light, *c*, has a value of $2.99792458 \times 10^8 \text{ m s}^{-1}$.

A **spontaneous (natural) process** is one that is able to take place in a system left to itself. No external action is required to make the process go, although in some cases the process may take a very long time.

Stalactites and **stalagmites** are limestone ($CaCO_3$) formations in limestone caves produced by the slow decomposition of $Ca(HCO_3)_2(aq)$.

A **standard cell potential, $E°$**, is the voltage of an electrochemical cell in which all species are in their standard states. (See also **cell potential**.)

Standard conditions of temperature and pressure (STP) refers to a gas maintained at a temperature of exactly 0 °C (273.15 K) and 760 mmHg (1 atm).

A **standard electrode potential, $E°$**, is the electric potential that develops on an electrode when the oxidized and reduced forms of some substance are in their *standard* states. Tabulated data are expressed in terms of the reduction process, that is, standard electrode potentials are standard reduction potentials.

The **standard enthalpy of formation, ΔH_f°**, of a substance is the enthalpy change that occurs in the formation of 1 mol of the substance in its standard state from the reference forms of its elements in their standard states. The reference forms of the elements are their most stable forms at the given temperature and 1 bar pressure.

The **standard enthalpy of reaction, $\Delta H°$**, is the enthalpy change of a reaction in which all reactants and products are in their standard states.

Standard Gibbs energy change, $\Delta G°$, is the Gibbs energy change of a process when the reactants and products are all in their standard states. The equation relating standard free energy change to the equilibrium constant is $\Delta G^\circ = -RT \ln K$.

The **standard Gibbs energy of formation, ΔG°_f**, is the standard free energy change associated with the formation of 1 mol of compound from its elements in their most stable forms at 1 bar pressure.

The **standard hydrogen electrode (SHE)** is an electrode at which equilibrium is established between H_3O^+ (a = 1) and H_2 (g, 1 bar) on an inert (Pt) surface. The standard hydrogen electrode is *arbitrarily* assigned an electrode potential of exactly 0 V.

The **standard molar entropy (S°)** is the absolute entropy evaluated when one mole of a substance is in its standard state at a particular temperature.

The **standard state** of a substance refers to that substance when it is maintained at 1 bar pressure and at the temperature of interest. For a gas it is the (hypothetical) pure gas behaving as an ideal gas at 1 bar pressure and the temperature of interest.

Standardization of a solution refers to establishing the exact concentration of the solution, usually through a titration.

A **standing wave** is a wave motion that reflects back on itself in such a way that the wave contains a certain number of points (nodes) that undergo no motion. A common example is the vibration of a plucked guitar string, and a related example is the description of electrons as matter waves.

Steel is a term used to describe iron alloys containing from 0 to 1.5% C together with other key elements, such as V, Cr, Mn, Ni, W, and Mo.

Step-reaction polymerization is a type of polymerization reaction in which monomers are joined together by the elimination of small molecules between them. For example, a H_2O molecule might be eliminated by the reaction of a H atom from one monomer with an —OH group from another.

A **stereocenter** is an asymmetric carbon atom.

In **stereoisomers**, the number and types of atoms and bonds in molecules are the same, but certain atoms are oriented differently in space. *Cis* and *trans* isomerism is one type of stereoisomerism; optical isomerism is another.

Stoichiometric coefficients are the coefficients used to balance an equation.

A **stoichiometric factor** is a conversion factor relating molar amounts of two species in a chemical reaction (i.e., a reactant to a product, one reactant to another, etc.). The numbers used in formulating the factor are stoichiometric coefficients.

Stoichiometric proportions refer to relative amounts of reactants that are in the same mole ratio as implied by the balanced equation for a chemical reaction. For example, a mixture of 2 mol H_2 and 1 mol O_2 is in stoichiometric proportions, and a mixture of 1 mol H_2 and 1 mol O_2 is not, for the reaction $2\ H_2 + O_2 \longrightarrow 2\ H_2O$.

Stoichiometry refers to quantitative measurements and relationships involving substances and mixtures of chemical interest.

A **strong acid** is an acid that is completely ionized in aqueous solution.

A **strong base** is a base that is completely ionized in aqueous solution.

A **strong electrolyte** is a substance that is completely ionized in solution.

A **structural formula** for a compound indicates which atoms in a molecule are bonded together, and whether by single, double, or triple bonds.

Structural isomers have the same number and kinds of atoms, but they differ in their structural formulas.

Sublimation is the passage of molecules from the solid to the gaseous state.

A **subshell** refers to a collection of orbitals of the same type. For example, the three 2*p* orbitals constitute the 2*p* subshell.

A **substance** has a constant composition and properties throughout a given sample and from one sample to another. All substances are either elements or compounds.

In a **substitution reaction,** an atom, an ion, or a group in one molecule is replaced by (substituted with) another.

A **substrate** is the substance that is acted upon by an enzyme in an enzyme-catalyzed reaction. The substrate is converted to products, and the enzyme is regenerated.

A **sugar** is a monosaccharide (simple sugar), a disaccharide, or an oligosaccharide containing up to ten monosaccharide units.

The **superoxide** ion has the structure

.

Superphosphate is a mixture of $Ca(H_2PO_4)_2$ and $CaSO_4$ produced by the action of H_2SO_4 on phosphate rock.

A **supersaturated** solution contains more solute than normally expected for a saturated solution, usually prepared from a solution that is saturated at one temperature by changing its temperature to one where supersaturation can occur.

Surface tension is the energy or work required to extend the surface of a liquid.

The **surroundings** represent that portion of the universe with which a system interacts.

A **suspension** is a heterogeneous fluid containing solid particles that are sufficiently large for sedimentation and, unlike colloids, will settle.

Synthesis gas is a mixture of CO(g) and H_2(g), generally made from coal or natural gas, that can be used as a fuel or in the synthesis of organic compounds.

A **system** is the portion of the universe selected for a thermodynamic study. (See also **open**, **closed**, and **isolated** systems.)

A **systematic error** is one that recurs regularly in a series of measurements because of an inherent error in the measuring system (e.g., through faulty calibration of a measuring device).

Temporary hard water (See **hard water**.)

A **terminal atom** is any atom that is bonded to only one other atom in a molecule or polyatomic ion.

A **termolecular process** is an elementary process in a reaction mechanism in which three atoms or molecules must collide simultaneously.

A **ternary compound** is comprised of *three* elements.

A **tertiary carbon** is attached to three other carbon atoms.

The **tertiary structure** of a protein refers to its three-dimensional structure—for example, the twisting and folding of coils.

The **theoretical yield** is the quantity of product *calculated* to result from a chemical reaction. (See also **actual yield** and **percent yield**.)

A **theory** is a model or conceptual framework with which one is able to explain and make further predictions about natural phenomena.

Thermal energy is energy associated with random molecular motion.

The **thermite reaction** is an oxidation–reduction reaction that uses powdered aluminum metal as a reducing agent to reduce a metal oxide, such as Fe_2O_3, to the free metal.

The **thermodynamic equilibrium constant, K**, is an equilibrium constant expression based on activities. In dilute solutions activities can be replaced by molarities and in ideal gases, by partial pressures in atm. The activities of pure solids and liquids are 1.

The **third law of thermodynamics** states that the entropy of a pure perfect crystal is zero at the absolute zero of temperature, 0 K.

The **titrant** is the solution that is added in a controlled fashion through a buret in a titration reaction. (See also **titration**.)

Titration is a procedure for carrying out a chemical reaction between two solutions by the controlled addition (from a buret) of one solution to the other. In a titration a means must be found, as by the use of an indicator, to locate the equivalence point.

A **titration curve** is a graph of solution pH versus volume of titrant. It outlines how pH changes during an acid–base titration, and it can be used to establish such features as the equivalence point of the titration.

A **torr** is a unit of pressure equal to the unit millimeter of mercury.

The **torsional** energy is the energy difference between the eclipsed and staggered forms of ethane.

The term ***trans*** is used to describe geometric isomers in which two groups are attached on opposite sides of a double bond in an organic molecule, or at opposite corners of a square in a square-planar complex, or at positions above and below the central plane of an octahedral complex. (See also **geometric isomerism**.)

Transition elements or **transition metals** are those elements whose atoms feature the filling of a d or f subshell of an *inner* electronic shell. If the filling of an f subshell occurs, the elements are sometimes referred to as inner transition elements.

The **transition state** in a chemical reaction is an intermediate state between the reactants and products. (See also **activated complex** and **reaction profile**.)

Triglycerides are esters of glycerol (1,2,3-propanetriol) with long-chain monocarboxylic (fatty) acids.

In a **triple covalent bond**, *three pairs* of electrons are shared between the bonded atoms. It is represented by a triple-dash sign ($\equiv$).

A **triple point** is a condition of temperature and pressure at which three phases of a substance (usually solid, liquid, and vapor) coexist at equilibrium.

Trouton's rule states that at their normal boiling points the entropies of vaporization of many liquids have about the same value: 87 J mol^{-1} K^{-1}.

A **unimolecular** process is an elementary process in a reaction mechanism in which a single molecule, when sufficiently energetic, dissociates.

A **unit cell** is a small collection of atoms, ions, or molecules occupying positions in a crystalline lattice. An entire crystal can be generated by straight-line displacements of the unit cell in the three perpendicular directions.

Unsaturated hydrocarbon molecules contain one or more carbon-to-carbon multiple bonds.

An **unsaturated solution** contains less solute than the solvent is capable of dissolving under the given conditions.

The **valence bond method** treats a covalent bond in terms of the overlap of pure or hybridized atomic orbitals. Electron probability (or electron charge density) is concentrated in the region of overlap.

Valence electrons are electrons in the electronic shell of highest principal quantum number, that is, electrons in the outermost shell.

The **valence-shell electron-pair repulsion (VSEPR) theory** is a theory used to predict probable shapes of molecules and polyatomic ions based on the mutual repulsions of electron pairs found in the valence shell of the central atom in the structure.

The **van der Waals equation** is an equation of state for nonideal gases. It includes correction terms to account for intermolecular forces of attraction and for the volume occupied by the gas molecules themselves.

The term **van der Waals forces** is used to describe, collectively, intermolecular forces of the London type and interactions between permanent dipoles.

One type of measure of an atomic size are **van der Waals radii.** van der Waals radii are strictly hard sphere radii measured using atomic distances in closest packed crystals.

Vaporization is the passage of molecules from the liquid to the gaseous state.

Vapor pressure is the pressure exerted by a vapor when it is in dynamic equilibrium with its liquid at a fixed temperature.

A **vapor-pressure curve** is a graph of vapor pressure as a function of temperature.

In a **vicinal dihalide**, a halogen adds across the double bond of an alkene, and the halogen atoms are bonded to adjacent carbons.

Viscosity refers to a liquid's resistance to flow. Its magnitude depends on intermolecular forces of attraction and in some cases, on molecular sizes and shapes.

A **volt (V)** is the SI unit for cell voltage. It is defined as 1 joule per coulomb.

A **voltaic (galvanic) cell** is an electrochemical cell in which a *spontaneous* chemical reaction produces electricity.

Water gas is a mixture of CO(g) and H_2(g), together with some of the noncombustible gases CO_2 and N_2, produced by passing steam [H_2O(g)] over heated coke.

A **wave** is a disturbance that transmits energy through a medium.

The **wavelength** is the distance between successive crests or troughs of a wave motion.

Wave mechanics is a form of quantum theory based on the concepts of wave–particle duality, the Heisenberg uncertainty principle, and the treatment of electrons as matter waves. Mathematical solutions of the equations of wave mechanics are known as **wave functions** (ψ).

Wave–particle duality was postulated by de Broglie and states that at times particles of matter have wave-like properties and vice versa. This was demonstrated in the diffraction pattern observed when electrons were directed at a nickel crystal.

A **weak acid** is an acid that is only partially ionized in aqueous solution in a reversible reaction.

A **weak base** is a base that it only partially ionized in aqueous solution in a reversible reaction.

A **weak electrolyte** is a substance that is only partially ionized in solution in a reversible reaction.

Work is a form of energy transfer between a system and its surroundings that can be expressed as a force acting through a distance.

A **zero-order reaction** proceeds at a rate that is *independent* of reactant concentrations. The sum of the concentration-term exponent(s) in the rate equation is equal to *zero*.

The **zero-point energy** is the lowest possible energy in a quantum mechanical system, such as the "particle-in-a-box" energy corresponding to $n = 1$ (page 318).

Zone refining is a purification process in which a rod of material is subjected to successive melting and freezing cycles. Impurities are swept by a moving molten zone to the end of the rod, which is cut off.

A **zwitterion** is a compound (for example, an amino acid or polypeptide) containing both acid and base groups. Zwitterions, at neutral pH, typically have simultaneously positively charged groups (cations) and negatively charge groups (anions).

G

Appendix

Answers to Concept Assessment Questions

Note: Your answers may differ slightly from those given here, depending on the number of steps used to solve a problem and whether any intermediate results were rounded off.

CHAPTER 1

Concept Assessment 1-1. No, an experimental result contrary to that predicted by a hypothesis is reason to reject a hypothesis, not its proof. **1-2.** The product (mg) is the same for the unknown and the "weights" of known mass, regardless of the value of g. The measured mass with a two-pan balance is the same on the moon as on Earth. The single pan electronic balance measures *weight*, which is converted to a "mass" reading. With such a balance calibrated on Earth, the "mass" will appear less when measured on the moon. **1-3.** To find the *one* temperature, substitute $t(°C) = t(°F)$ into the equation $t(°F) = \frac{9}{5}t(°C) + 32$. Solve for $t(°F)$ to obtain the value -40 °F; thus -40 °F $= -40$ °C. **1-4.** The volume of wood is $1000\ g/(0.68\ g\ cm^{-3}) = 1470\ cm^3$. The wood displaces its own mass of water—1000 g, which has a volume of 1000 cm^3. The fraction of wood under water is $1000/1470 = 0.68$. **1-5.** Yes to both questions. A measuring instrument might yield precise readings but be incorrectly calibrated—measurements might agree with one another but their average might not agree with the actual value. Measurements with an imprecise instrument might differ widely from the actual value, yet their average might, by chance, agree with the actual value. **1-6.** The relationship 1 in $= 2.54$ cm is a definition—an *exact* quantity. A more precise relationship between meters and inches is 1 m $= 100\ cm \times (1\ in/2.54\ cm) = 39.370079$ in.

CHAPTER 2

Concept Assessment 2-1. Helmont assumed, incorrectly, that the tree interacted with its surroundings only through the soil, sunlight, and watering. The tree also interacted with the atmosphere, that is, with carbon dioxide gas (see photosynthesis, page 273). **2-2.** The *final* mass, magnesium bromide plus unreacted bromine, equals the *initial* mass: 4.15 g + 82.6 g = 86.8 g, but without knowing the mass of unreacted bromine we cannot deduce the mass of magnesium bromide. **2-3.** The discovery of cathode rays (electrons) refuted the idea that atoms are indivisible. The discovery of isotopes refuted the idea that all atoms of an element are alike in mass. The idea that atoms combine in simple numerical ratios remains valid. **2-4.** The exception is the protium atom, $^{1}_{1}H$, the most abundant isotope of hydrogen. It consists of a lone proton as the atomic nucleus. **2-5.** The weighted average atomic mass of 51.9961 u, almost exactly 52 u, suggests that chromium might exist exclusively as $^{52}_{24}Cr$ atoms. Another possibility (which, in fact, is the case) is that chromium exists as a mixture of isotopes whose weighted average atomic mass is 51.9961 u. For zinc, we should conclude two or more isotopes. The weighted average atomic mass, 65.409 u, is too far from 65 u to suggest a single isotopic mass. **2-6.** If all naturally occurring Au atoms have the mass 196.967g Au/N_A, they must all be $^{197}_{79}Au$, with no isotopes. If no Ag atom has the mass 107.868g Ag/N_A, there must be two or more naturally occurring isotopes. (In fact there are two: $^{107}_{47}Ag$ and $^{109}_{47}Ag$.)

CHAPTER 3

Concept Assessment 3-1. For the *molecular* formula count the atoms in the condensed structural formula given: $C_4H_6O_2$. The *empirical* formula has the same ratio but with the smallest possible integers: $C_2H_3O_2$. Visualize the *structural* formula in terms of that of butane in Figure 3-2(a). Replace the —CH_3 groups at the two ends of the butane structure with —COOH groups (see structural formula of acetic acid in Figure 3-1). For the simplest *line-angle* formula, draw a line to represent $H_2C—CH_2$ and at an angle at each end of the line attach a —COOH group. **3-2.** Compare the other four quantities to **(d)**—the 20.000g brass weight.
(a) 0.50 mol O_2 = 16.00 g; this might be the smallest mass but cannot be the largest.
(b) 2.0×10^{23} Cu atoms $= 1/3$ mol Cu ≈ 21 g; this is now the largest mass. **(c)** 1.0×10^{24} H_2O molecules is more than 1.5 mol $H_2O > 27$ g; this is now the largest mass. **(e)** the mass of 1.0 mol Ne = 20. g. Conclusion: greatest mass, **(c)**; smallest mass, **(a)**. **3-3.** C contributes the greatest number of atoms—13—and Cl contributes the greatest mass. A Cl atom, of which there are six, has nearly three times the mass of a C atom. **3-4.** Obtain relative numbers of atoms in the formula by multiplying the molar mass by the mass fractions of the elements. In Example 3-5, for example, mol C $= 0.6258 \times 230\ g \times (1\ mol\ C/12.011\ g) = 11.98$ mol C. Similarly, obtain 21.97 mol H and 3.995 mol H. Thus, the molecular formula is $C_{12}H_{22}O_4$ and the empirical formula is $C_6H_{11}O_2$. **3-5** In each combustion, 1 mol CO_2 forms for every mole C and 1 mol H_2O for every 2 mol H. Determine these amounts for each combustion:
(a) 5 mol CO_2 and 2 mol H_2O; **(b)** 1.25 mol CO_2 and 2.5 mol H_2O; **(c)** 1 mol CO_2 and 1.5 mol H_2O; **(d)** 6 mol CO_2 and 3 mol H_2O. Thus, C_6H_5OH [response **(d)**] produces a greatest number of moles (and thus mass) of both CO_2 and H_2O. **3-6.** The O.S. of N in NH_3 is -3. The O.S. of N is higher in H_2NNH_2; it is -2. Note also that the molar mass of N_2H_4 is 32 g/mol. **3-7.** No. The greatest mass ratio of H_2O to CO_2 is found in CH_4, which has the highest percent H of all hydrocarbons; and its combustion produces only 2 mol H_2O (36 g) to 1 mol CO_2 (44 g).

CHAPTER 4

Concept Assessment 4-1. (a) The product is $O_2(g)$, not O(g). **(b)** The product is $O_2(g)$ exclusively, not a mixture of O(g) and $O_2(g)$. **(c)** The product is KCl(s), not KClO(s). **4-2 (a)** incorrect (3 mol S per *2 mol* H_2S) **(b)** incorrect (stoichiometric coefficients refer to moles, not grams) **(c)** correct (1 mol H_2O/1 mol H_2S is the same as 2 mol H_2O/2 mol H_2S) **(d)** correct (2 of every 3 mole of S on the left are in 2 mol H_2S, yielding 3 mol S on the right) **(e)** incorrect (3 moles of reactants yield 5 moles of product) **(f)** correct (no atoms can be created or destroyed in the reaction) **4-3.** The reaction producing the greatest mass of $O_2(g)$ per gram of reactant is the one having the reactant of lowest molar mass. Clearly that reactant is $NH_4NO_3(s)$ in reaction **(a)**. **4-4 (a)** Tripling the solution volume reduces the molarity to 1/3 of its initial value: 0.050 M NaCl. **(b)** Reducing the volume from 250.0 mL to 200.0 mL increases the molarity by 5/4, that is, to 1.000 M $C_{12}H_{22}O_{11}$. **(c)** The molarity of the first solution is reduced to 1/3, to 0.0900 M KCl; that of the second is reduced to 2/3, to 0.0900 M KCl. The total molarity of the final solution is 0.180 M KCl. **4-5.** The balanced equation is $4\ NH_3(g) + 5\ O_2(g) \longrightarrow 4\ NO(g) + 6\ H_2O(l)$. Starting with 1.0 mol each of NH_3 and O_2, the limiting reactant is O_2. The amounts of products are 0.8 mol NO and 1.2 mol H_2O. The only true statement is **(d)** all the $O_2(g)$ is consumed. **4-6.** The answer must be consistent with the following facts.

(1) The factor 0.90 must appear twice in the setup (which can include $0.90 \times 0.90 = 0.81$); **(2)** CH_3Cl is an intermediate and does not enter in; **(3)** the only molar masses needed are those of CH_4 (16 g/mol) and CH_2Cl_2 (85 g/mol). The correct response is **(a)**.

CHAPTER 5

Concept Assessment 5-1 (1). (e) 0.025 M $RbNO_3$, the only strong electrolyte of the group. **(2). (a)** a strong electrolyte with a total ion concentration of 0.024 M. **5-2.** Predicted as soluble based on guidelines in Table 5.1: **(a), (c), (g)**. Predicted as insoluble based on Table 5.1: **(b), (e), (h), (i)**. Inconclusive based on Table 5.1: **(d)** Li_2CO_3 might be soluble (Li^+ is a group 1 cation), but also might be one of the exceptions referred to in Table 5.1. **(f)** No data are available in Table 5.1 concerning permanagnates, so the solubility of $Mg(MnO_4)_2$ is uncertain. **5-3.** $H_2O(l)$ is suitable for $K_2CO_3(s)$ and $ZnSO_4(s)$, and HCl(aq) is suitable for CaO(s) and $BaCO_3(s)$. $H_2SO_4(aq)$ would not be suitable for CaO(s) and $BaCO_3(s)$ because $CaSO_4(s)$ and $BaSO_4(s)$ might precipitate. **5-4.** No reaction would occur in **(a)**. Two reduction half-reactions and no oxidation half-reaction. Reaction could occur under appropriate conditions in **(b)** because $Cl_2(g)$ undergoes both oxidation and reduction. **5-5.** This can occur as seen, for example, in the reverse of the disproportionation reaction directly above on this page. **5-6.** An inaccurate statement. An oxidizing agent is necessary to oxidize $Cl^-(aq)$ to $Cl_2(g)$, but neither HCl(aq) or NaOH(aq) is an oxidizing agent. **5-7.** An exactly neutral NaCl(aq) formed when 3.11×10^{-3} mol each of H^+ and OH^- ions neutralize one another.

CHAPTER 6

Concept Assessment 6-1. A water siphon passes over a "hump" from a pool of water at a higher level to a receiver at a lower level. After the siphon is initially filled with water, the pressure of the atmosphere pushes water over the hump, beyond which the water flows freely. In a suction pump, air pressure pushes water up a partially evacuated pipe. **6-2. (b) 6-3. (a) 6-4.** The direct proportionality of V and T must be based on an absolute temperature scale. While a change from 100 K to 200 K produces a doubling of V, a change from 100 °C to 200 °C produces only a 27% increase: $[(200 + 273)/(100 + 273)] = 1.27$. **6-5.** Consider these facts. **(1)** V is directly proportional to the number of moles of $O_2(g)$, and this must be 60.0 g O_2/32.00 g O_2 mol^{-1}. Only responses **(c)** and **(d)** meet this requirement. **(2)** The effect of changing P and T on the STP-volume must be expressed through the product $[(760\ mmHg/825\ mmHg) \times (303\ K/273\ K)]$. The only correct response is **(d)**. **6-6. (a)** 0.667 L $SO_2(g)$/1.00 L $O_2(g)$, because the actual P and T are immaterial as long as the two gases are compared at the same t and P. **(b)** The 0.667 L $SO_2(g)$ has to be adjusted for the an increase in T (by the factor 298 K/273 K) and a decrease in P (by the factor 760 mmHg/745 mmHg), leading to $V = 0.743$ L $SO_2(g)$. **6-7.** The correct responses—**(b)** and **(e)**—follow from basic ideas. Dalton's law of partial pressures dictates that P_{He} is not affected by any other gases present, and addition of 0.50 mol H_2 (1.0 g) will increase the total mass of gas by 1.0 g, independent of anything else that may happen. By simple estimates the other three statements can be shown to be false. **6-8.** He(g) at 1000 K has twice the u_{rms} as at 250 K (change T to $4T$ in equation 6.20). At 250 K, u_{rms} of $H_2(g)$ exceeds that of He(g) by the factor $\sqrt{2}$ (change M to $\frac{1}{2}M$ in equation 6.20). The two-fold increase in the first case exceeds the $\sqrt{2}$-fold increase in the second. He(g) at 1000 K has a greater u_{rms} than $H_2(g)$ at 250 K. **6-9.** The correct responses are **(a)** and **(c)**. The average kinetic energy of gas molecules depends only on T, and to two significant figures the mass of 0.50 mol He is the same as that of 1.0 mol H_2. **6-10.** Rearrange equation (6.14) to the form $R = MP/dT$. Substitute molar masses, $P = 1$ atm (exactly), $T = 293.2$ K, and the density data. Solve for three values of R and see how closely they conform to the ideal gas constant $R = 0.08206$ L atm mol^{-1} K^{-1}. Increasing adherence to ideal gas behavior: $OF_2(R = 0.0724) < NO(R = 0.08194) < O_2(R = 0.08200)$.

CHAPTER 7

Concept Assessment 7-1. Dynamite exploding in an underground cavern is a close approximation to an isolated system. Titration of an acid with a base is an open system. A steam-filled cylinder in a steam engine with all valves closed constitutes a closed system. **7-2.** Basic principle: law of conservation of energy. Assumptions: no heat loss to surroundings, *d* and *sp. ht.* of $H_2O(l)$ independent of T. Because the mass of hot water is twice that of the colder water, the initial temperature difference of 60.00 °C is divided into a 40.00 °C warming of the cold water and a 20.00 °C cooling of the hot water; final $T = 50.00$ °C. **7-3.** The ΔT of a fixed mass of substance is inversely proportional to its specific heat; thus the object with the smaller ΔT has the greater specific heat. The second question requires us to recognize the difference in enthalpy of transition for the solid and liquid form of water. The enthalpy of fusion for ice is less than the enthalpy of vaporization for the liquid, meaning that the amount of heat required to vaporize water is greater than that for ice. **7-4.** This is accomplished by adding a measured amount of a substance in which the heat of reaction is known. **7-5.** This is a closed system. Since the pressure dropped while the volume remained constant then the temperature must have decreased. The internal energy of the system decreased. Therefore the energy transferred across the boundary was in the form of heat. The direction of energy transfer was from the system to the surroundings. **7-6.** The balloon feels warm because the dissolution of $NH_3(g)$ in $H_2O(l)$ is exothermic, $q < 0$. The balloon shrinks because the atmosphere (surroundings) does work on the system, $w > 0$. **7-7.** In the bottom row T is uniform throughout the object while in the top row the object is hotter at the edges than in its interior. Heating in the top row is irreversible; the process is far from equilibrium. The bottom row represents reversible heating; removal of just a tiny amount of heat can change heating to cooling. **7-8.** Enthalpy is a function of state. When a process returns a system to its initial state H returns to its initial value, meaning that $\Delta H = 0$. **7-9.** The enthalpy change in forming 1 mol $C_2H_2(g)$ from its elements is represented by the top line; that for forming 1 mol $C_2H_4(g)$ is the next line down. Both of these lines are above the broken line representing $\Delta H = 0$. The formation of 1 mol C_2H_6 has $\Delta H < 0$ and is the first line below the broken line. $\Delta H°$ for the reaction of interest is represented by the distance between the first and third lines. **7-10.** Yes, this can be done. The additional data needed are heat capacities as a function of T. The procedure is outlined in Figure 7-16.

CHAPTER 8

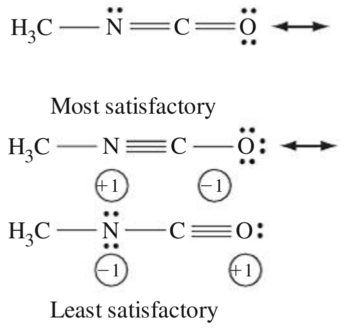
Concept Assessment 8-1. The wavelength of red light is about 700 nm (see Fig. 8-3). Since frequency and wavelength are reciprocally related, doubling ν halves λ. The frequency-doubled light will have a wavelength about 350 nm—light in the near ultraviolet not visible to the human eye. **8-2.** By studying emission spectra from the collision, scientists hope to identify the elements present in the comet and also on Jupiter's surface. **8-3.** The threshold wavelength is 91.2 nm. Using 70.0 nm light as compared to 80.0 nm light produces more energetic electrons. Each photon produces one electron, and the number of electrons produced depends on the intensity (number of photons) of the light, provided its wavelength is less than the threshold wavelength. **8-4.** The transition $n = 1$ to $n = 4$ corresponds to the greatest ΔE, but it involves *absorption* of a photon not emission. Photons are emitted in the other two transitions, with the transition $n = 4 \longrightarrow n = 2$ corresponding to the greater ΔE and hence shortest wavelength. **8-5.** If the wavelengths are the same then the momenta are the same (equation 8.10). The speed of the proton will have to be 1/2000th of the speed of the electron (that is, $m_p \times u_p = m_e \times u_e$, and $u_p = u_e \times m_e/m_p = u_e \times 1/2000$). **8-6.** The state $n = 2$ has a peak $\frac{1}{4}$ of the length from either end of the box, corresponding to the greatest probability of the particle being at those points. **8-7.** An orbital with three angular nodes has $\ell = 3$; it is an f orbital. One radial node makes for a total of four nodes, and since the total number of nodes is $n - 1$, n must be 5. The orbital is a $5f$. **8-8.** The compound is arsenic. The ground state is $4s^2 3d^{10} 4p^3$ with all three arrows pointing in the same direction, one in each box. The anion is adding one more arrow to one of the $4p$ boxes pointing in the opposite direction.

CHAPTER 9

Concept Assessment 9-1. (a) Ne **(b)** N^{3-} or P^{3-} **(c)** Zn^{2+}, Cd^{2+}, or Hg^{2+} **9-2.** Z_{eff} increases and atomic radius decreases with increasing Z. The blue axis represents Z_{eff} and the blue line, Z_{eff} as a function of Z. The red axis represents atomic radius and the red line, atomic radius as a function of Z. **9-3**. **(a)** B (at the top of group 13) **(b)** Cl (at the right end of the third period) **(c)** P^{3-} in period 3, group 15 (strong electron repulsions in an anion of high negative charge) **(d)** Tl (at the bottom of group 13) **9-4. (a)** C (smallest group-14 atom, at the top of the group) **(b)** Kr (noble gas element in group 18) **(c)** Se (lower ionization energy than Br based on the expected trend; lower than As for the same reason as in the P/S comparison on page 377) **9-5. (a)** group 17 (the smallest atoms in their periods) **(b)** group 2 (a filled *ns* subshell and essentially no affinity for an additional electron) **(c)** group 18 (noble gases have all shells and subshells closed) **9-6 (a)** scandium (Sc^{3+} has noble gas electron configuration) **(b)** tellurium (Te^{2-} has a noble gas electron configuration) **(c)** manganese (Mn^{2+} has the electron configuration $[Ar]3d^5$) **9-7 (a)** thallium **(b)** nitrogen **(c)** rubidium **(d)** iodine **(e)** aluminum

CHAPTER 10

Concept Assessment 10-1. The first and last symbols are acceptable; each has six dots with two unpaired. The unacceptable symbols have seven and five dots. **10-2.** The bonds are all covalent, with one being coordinate covalent. **10-3.** groups 14, 15, and 16 (for example, the elements C, N, O, P, and S) **10-4. (a)** Br **(b)** Be **(c)** P **10-5.** If covalent bonds between atoms involve equal contributions from all the bonded atoms, there are no formal charges. Where coordinate covalent bonds are formed there will be formal charges. A polyatomic ion must have at least one atom with a formal charge, consistent with the charge on the ion. **10-6.** We can draw two possible Lewis structures. One structure has no formal charges. In the other structure, one of the O atoms (the one bonded to H) has a formal charge of +1 and the other has a formal charge of −1. The structure with formal charges is considered to be unimportant and so we never represent the structure of CH_3CO_2H as a resonance hybrid. **10-7.** The structure of the SO_2 molecule is best represented as , and so the sulfur–oxygen bonds are best thought of as double bonds. **10-8.** ICl_2^- is a *linear* anion with five electrons pairs around the I atom (AX_2E_3). ICl_2^+ is a *bent* cation with four electron pairs around the I atom (AX_2E_2). The difference of one pair of electrons produces a completely different electron-group geometry and geometric shape. **10-9.**



10-10. In NH_3 the lone pair of electrons on the N atom pulls electron density away from the H atoms, creating a large resultant dipole moment. In NF_3 the highly electronegative F atoms pull electron density away from the N atom, producing highly polar N—F bonds that counteract the effect of the nitrogen lone pair and a greatly reduced resultant dipole moment. **10-11.** Both the linear NO_2^+ cation and bent NO_2^- anion exhibit resonance that involves double bond character in the N—O bonds. However, electrons in the NO_2^+ cation will be more tightly held by the center of positive charge, leading to shorter N-to-O bond lengths in NO_2^+ than in NO_2^-.

CHAPTER 11

Concept Assessment 11-1. The cation CH_3^+ is isoelectronic with BH_3 and has three pairs of electrons around the C atom; we expect sp^2 hybridization. In the anion CH_3^- there are four electron pairs suggesting sp^3 hybridization, as in CH_4. **11-2.** The sp^3d^2 hybridization scheme corresponds to six electron pairs around a central atom. Similar to PF_5 in the period above it, we expect the compound AsF_5. Now imagine adding F^- to AsF_5 to create $[AsF_6]^-$, which has 6 electron pairs around the As atom and requires sp^3d^2 hybridization. **11-3.** Five bonding electron groups can be accommodated by sp^3d hybridization, but the distribution would be trigonal bipyramidal. What is needed is sp^3d^2 hybridization in the species AX_5E. The lone-pair electrons are directed to a corner of an octahedron, and the remaining five positions determine the molecular geometry—square pyramidal. **11-4.** To complete the octets of the N atoms, they must retain a lone pair of electrons, form a double bond between themselves, and a single bond to a H atom. The hybridization of the N atoms is sp^2. **11-5.** The H_2^+ ion is formed by removal of one electron from H_2—a larger energy requirement than promoting a σ_{1s} electron to the σ_{1s}^* MO in the excited state of H_2. On the other hand, the bond order in H_2^+ is 0.5 and 0 in the excited state of H_2. H_2^+ is a stable species and the excited state of H_2 is not. **11-6.** No. For example, the double bond in C_2 is made up of two π bonds and no σ bond (see Figure 11-26). **11-7.** The molecule NeO is isoelectronic with F_2 and should have a bond order of 1. We expect it to be stable, but it has never been observed. **11-8.** In HCO_2^- three atoms provide *p* orbitals for π bonding, just as in ozone. In the NO_3^- anion four atoms provide *p* orbitals. The delocalized π bonding in HCO_2^- is different than in NO_3^-.**11-9.** GaN, a combination of group 13 and group 15 elements, is a semiconductor; this combination is equivalent to a group 14 semicondictor like Si or Ge.

CHAPTER 12

Concept Assessment 12-1. The intermolecular interactions are both London dispersion forces and hydrogen bonds. In substances with small molecules, hydrogen bonding usually dominates. **12-2.** Because the ball drops faster through it, the 10W oil is less viscous than the 40W oil. Viscosity is inversely proportional to *T*, and the lower weight oil (10W) is preferred for low-temperature use (where higher weight oils might solidify). In hot desert regions higher weight oils (40W) are preferred because light-weight oils might become so mobile as to lose their lubricating properties. The strengths of intermolecular forces are directly related to viscosity, and hence the higher viscosity 40W oil has the stronger intermolecular forces. **12-3.** Because of the different elevation (and barometric pressure) between landlocked, mountainous Switzerland and sea-level Manhattan Island, the lower boiling temperature results in a longer cooking time. **12-4.** Hydrogen bonding occurs in NH_3 but not in N_2, resulting in stronger intermolecular attractions and consequently lower vapor pressures, a higher boiling point, and a higher critical temperature in NH_3 than in N_2. **12-5.** The greater number of electrons (much larger molar mass) in CCl_4 causes the intermolecular attractions (London dispersion forces) to outweigh the effect of the polar bonds in CH_3Cl. **12-6.** Dew forms in the condensation of $H_2O(g)$ to $H_2O(l)$ and frost from the deposition of $H_2O(g)$ as $H_2O(s)$. Both processes are exothermic and give off heat to the surroundings—more heat in frost formation, because $\Delta H(\text{deposition}) = \Delta H(\text{condensation}) + \Delta H(\text{freezing})$. **12-7.** Wet books are placed in a cold, evacuated chamber. Moisture in the books freezes and the ice that is formed sublimes to $H_2O(g)$. This process avoids heating and involves a minimum of handling of the damaged books. **12-8.** According to the Bragg equation, $n\lambda = 2d \sin \theta$, if the extra distance traveled by the diffracted wave ($2d \sin \theta$) is to remain the same when *n* is doubled, the wavelength of the wave must be halved, so that $2n(\lambda/2) = n\lambda$. The required multiple is $\frac{1}{2}$. **12-9.** The fcc unit cell contains four C_{60} molecules. The unit cell has four octahedral and eight tetrahedral holes occupied by 12 K atoms. The formula based on the unit cell is $K_{12}(C_{60})_4$, and the molecular formula is $K_3(C_{60})$.

CHAPTER 13

Concept Assessment 13-1. 3.011×10^{23}. **13-2.** Concentrations are independent of temperature if based solely on mass or temperature-independent properties related to mass, specifically, mass percent, molality, mole fraction, and mole percent. Concentrations based on volumes—volume percent and molarity—are temperature dependent. **13-3.** HCl is undissociated in $C_6H_6(l)$, and the concentration of HCl in $C_6H_6(l)$ should closely follow $P_{HCl(g)}$ above the solution. On the other hand, HCl(g) reacts with $H_2O(l)$ to produce $H_3O^+(aq)$ and $Cl^-(aq)$. The relationship between $P_{HCl(g)}$ and the aqueous concentrations of ions is more complex. **13-4.** Start with $(P_A^\circ - P_A)/P_A^\circ = x_B$. Note that $(P_A^\circ - P_A)/P_A^\circ = 1 - (P_A/P_A^\circ)$. According to Raoult's law, $P_A = x_A P_A^\circ$, which means that $P_A/P_A^\circ = x_A$. Thus, we arrive at the true statement that $1 - x_A = x_B$. **13-5.** This will happen if both components in an ideal solution have the same vapor pressure. The vapor pressure of the solution will be independent of the solution composition and the line will be parallel to the composition axis. The likelihood of this happening is not very great, although it might be found at one particular temperature where the vapor pressure curves of two liquids cross. **13-6.** The similarities are that two different solutions are involved, water is transported from the more dilute to the more concentrated solution, and the process continues until the two solutions have the same concentration. The chief difference is that water is transported via the vapor phase in Figure 13-16a and through a semipermeable membrane in Figure 13-17. **13-7.** If Figure 13-19 were based on water rather than some other solvent, the two fusion curves would have *negative* rather than positive slopes. However, there would still be a freezing-point depression and a boiling-point elevation. **13-8.** When enough NaCl is present to depress the freezing point to $-21\ °C$, the NaCl(aq) is saturated. Any solute added beyond this point remains as undissolved NaCl(s) and can have no further effect on the freezing point of the solution.

CHAPTER 14

Concept Assessment 14-1. In the reaction $N_2(g) + 3\,H_2(g) \longrightarrow 2\,NH_3(g)$, compared to the rate of disappearance of N_2, the rate of disappearance of H_2 is three times as great and the rate of formation of NH_3 is twice as great. **14-2.** If the initial and instantaneous rates of reaction are initially equal and remain so throughout a reaction, the concentration-time graph must be a straight line with a negative slope, as seen in Figure 14-3. **14-3.** If the reaction were first order the initial rate would double and if second order, quadruple, thus $1 < \text{order}\,(m) < 2$. More precisely, $2^m = 2.83$ and $m = 1.50$ (solve this equation for m: $m \log 2 = \log 2.83$). **14-4.** All four graphs can be plotted on the same sheet of paper. For example, take $[A]_0 = 3.0$ M and $k = 0.20\ s^{-1}$ as the larger of two rate constants and $k = 0.10\ s^{-1}$ as the smaller. Both concentration vs. time graphs will resemble Figure 14-5, but after starting at the same point, $[A]_0 = 3.0$ M, the one with the larger k has a shorter half-life and falls off more rapidly than the other. The two plots of $\ln k$ vs. t are straight lines, both starting at $\ln [A]_0 = \ln 3.0 = 1.10$, and having negative slopes, the steeper slope for the larger value of k. **14-5. (a)** If the plot was linear, the reaction would be zero order; **(b)** Look at successive half-lives. If $t_{1/2}$ is constant, the reaction is first order; **(c)** Look at successive half-lives. If $t_{1/2}$ doubles each time, the reaction is second-order. **14-6 (a)** This condition can exist. The reaction is exothermic (similar to Figure 14-10). **(b)** This condition can exist, and the reaction is endothermic (imagine flipping the reaction profile in Figure 14-10 from left to right). **(c)** This condition cannot exist; E_a for an exothermic cannot be less than ΔH. **(d)** This condition can exist; its only distinction is that there is no heat of reaction. **(e)** This condition cannot exist; E_a cannot be negative. **14-7.** Consider this equation from Figure 14-12: $E_a = R \times (-\text{slope of } \ln k \text{ vs. } 1/T)$. The greater the value of E_a, the greater the slope of the graph and the more rapidly the rate of reaction changes with temperature. **14-8.** The means are not the same. The increase in reaction rate caused by the presence of a catalyst is most likely because of a different reaction mechanism that lowers the reaction barrier. The increase in the rate of reaction caused by an increase in temperature is due to more molecules with kinetic energy greater than the barrier; more collisions occur per unit time.

CHAPTER 15

Concept Assessment 15-1. (a) represents solubility-phase equilibrium; **(b)** phase equilibrium; **(c)** chemical equilibrium.

15-2. $Q = \dfrac{a_{Cu^+(aq)}a_{H_2(g)}}{a_{Cu(s)}a^2_{H^+(aq)}} = \dfrac{[Cu^{2+}]P_{H_2}}{[H^+]^2}$.

15-3. Into the expression $K = [B]/[A]$, substitute $[B] = 54 - [A]$ and the given value of K; solve for [A] and [B]. If $K = 0.02$, [A] (open circles) $= 53$ and [B] (filled circles) $= 1$. If $K = 0.5$, $[A] = 36$ and $[B] = 18$. If $K = 1$, $[A] = [B] = 27$. **15.4.** If $K > 1$ for the 2nd reaction, K for the 1st reaction will be the larger of the two, but if $K < 1$ for the 2nd reaction, K for the 1st reaction will be the smaller of the two. **15-5.** Reverse given equation (invert its K value). To that equation add $CH_4(g) + H_2O(g) \rightleftharpoons CO(g) + 3\,H_2(g)$; CO(g) cancels and the overall equation is the one we seek; its K is the ratio of the other two K values. **15-6.** The balanced equation is sufficient to determine the outcome of a reaction that goes to completion. If the reaction is reversible and reaches a state of equilibrium, the value of K is required as well. **15-7. (a)** incorrect: would require that CO(g) and $H_2O(g)$ be completely consumed—impossible with $K_p = 10.0$. **(b)** incorrect: would be violation of the law of conservation of mass. **(c)** incorrect; would require the consumption of some $CO_2(g)$, but the direction of net change must be in the forward reaction. **(d)** correct: an outcome that would result from a net change in the forward direction. **(e)** incorrect: sufficient data are given to calculate the composition of the equilibrium mixture. **15-8.** Even though the pressure increases because of the addition of an inert gas, the reaction will shift to the right since the volume of the reaction vessel decreased. **15-9. (a)** True—more $H_2(g)$ will form at the expense of the $H_2S(g)$ and $CH_4(g)$. **(b)** False—an inert gas has no effect on a constant-volume equilibrium condition. **(c)** True—K changes with T and so does the composition of the equilibrium mixture. **(d)** Uncertain—the partial pressures of $H_2S(g)$ and $CH_4(g)$ will rise because a net reaction occurs to the left, but the increase in partial pressures of $CS_2(g)$ and $H_2(g)$ caused by forcing these two gases into a smaller volume will be at least partly offset by the equilibrium shift to the left. **15-10.** Equilibrium shifts in the forward direction, the endothermic reaction. Student B, by holding the beaker, stimulates heat flow into the reaction mixture, probably achieving a higher yield of product.

CHAPTER 16

Concept Assessment 16-1. (a) is a conjugate acid/base pair; HCO_3^- can transfer a proton to a base (e.g., OH^-) yielding CO_3^{2-}, and CO_3^{2-} can react with an acid (e.g., H_3O^+) to reform HCO_3^-. **(b)** is not a conjugate acid/base pair; SO_4^{2-} can be produced from HSO_3^- only through an oxidation process not in an acid–base reaction. **(c)** is not a conjugate acid/base pair; it is a pair of unrelated acids. **(d)** yes; **(e)** no. **16-2.** With $pH = \log[H_3O^+]$, the vast majority of solutions would have negative pH values. It is more convenient to incorporate the negative sign in the definition than to carry it in individual pH values. With $pH = -\ln[H_3O^+]$ the close relationship between pH and the powers of ten used in scientific notation would be completely lost. (The desire to establish this relationship was why the pH concept was devised in the first case.) **16-3.** A concentrated solution of a weak acid may often have a lower pH than a dilute solution of a strong one. For example, the pH of 0.10 M $HC_2H_3O_2$—calculated as $pH = 2.89$ in Example 16-6—is lower than the pH of 0.0010 M HCl. **16-4.** The bottle labeled $K_a = 7.2 \times 10^{-4}$ contains the more acidic solution. The bottle labeled $K_a = 1.9 \times 10^{-5}$ has the acid with the larger pK_a. The relevant equations are $^+NH_3CH_2CH_2NH_3^+(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + NH_2CH_2CH_2NH_3^+(aq)$ $pK_1 = 6.85$ and $NH_2CH_2CH_2NH_3^+(aq) + H_2O(l)$ $H_2O(l) \rightleftharpoons H_3O^+(aq) + NH_2CH_2CH_2NH_2(aq)$ $pK_2 = 9.92$. From equation (16.18), the values of the base ionization constants are $pK_{b_1} = 14.00–9.92 = 4.08$ and $pK_{b_2} = 14.00–6.85 = 7.15$.

The base ionization reactions are $NH_2CH_2CH_2NH_2(aq) + H_2O(l) \rightleftharpoons NH_2CH_2CH_2NH_3^+(aq) + OH^-(aq)$ $pK_{b_1} = 4.08$ and $NH_2CH_2CH_2NH_3^+(aq) + H_2O(l) \rightleftharpoons {}^+NH_3CH_2CH_2NH_3^+(aq) + OH^-(aq)$ $pK_{b_2} = 7.15$ $^+NH_3CH(CH_3)COOH + H_2O \rightleftharpoons NH_3CH(CH_3)COO^- + H_3O^+$ $pK_a = 2.34$ $^+NH_3CH(CH_3)COO^- + H_2O \rightleftharpoons NH_2CH(CH_3)COO^- + H_3O^+$ $pK_a = 9.87$

$pK_{b_1} = 14.00–2.63 = 11.37$

$pK_{b_2} = 14.00–9.87 = 4.13$

$NH_2CH(CH_3)COO^- + H_2O \rightleftharpoons {}^+NH_2CH(CH_3)COO^- + OH^-$ $pK_{b_1} = 4.13$

$^+NH_3CH(CH_3)COO^- + H_2O \rightleftharpoons {}^+NH_3CH(CH_3)COOH + OH^-$ $pK_{b_1} = 11.37$.

16-6. Consider HPO_4^{2-}, which can act as an acid: $HPO_4^{2-}(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + PO_4^{3-}(aq)$, $K_a = 4.2 \times 10^{-13}$ or as a base: $HPO_4^{2-}(aq) + H_2O(l) \rightleftharpoons H_2PO_4^-(aq) + OH^-(aq)$ $K_b = K_w/K_a = 1.00 \times 10^{-14}/4.2 \times 10^{-13} = 2.4 \times 10^{-2}$. Because K_b is much greater than K_a, $HPO_4^{2-}(aq)$ is basic. In a similar way, $H_2PO_4^-(aq)$ is seen to be acidic. Thus, depending on K values, ions in aqueous solutions may have pH values ranging from acidic to neutral to basic. **16-7.** We should expect pK_a for *ortho*-chlorophenol to be smaller than for phenol because of the electron-withdrawing effect of the Cl atom. (Its pK_a is 8.55 compared with 10.00 for phenol.) **16-8.** Picture three Br atoms joined by single bonds to a Fe(III) atom on which there is also a lone pair of electrons: Br_3Fe: Now imagine that a Br_2 molecule dissociates into Br^+ and Br^- ions. The electron-deficient Br^+, a Lewis acid, attaches to the lone-pair electrons of Fe(III), a Lewis base, forming $[FeBr_4]^+$. The final product is $[FeBr_4]^+Br^-$.

CHAPTER 17

Concept Assessment 17-1. (a) no; NH_4Cl lowers the pH through the common-ion effect **(b)** yes, but only slightly. Diethylamine is a somewhat stronger base than NH_3, but only a rather small amount is being added. **(c)** no; HCl is a strong acid that will neutralize some of the NH_3, producing an aqueous solution of NH_3 and NH_4Cl. **(d)** no; since the added $NH_3(aq)$ is more dilute than the 0.10 M $NH_3(aq)$ the overall solution will be 0.075 M $NH_3(aq)$. **(e)** yes; $Ca(OH)_2(s)$ is a strong base. **17-2.** benzoic acid/ benzoate with a 1:2 ratio. **17-3. (a)** yellow; a low pH **(b)** yellow; a CH_3COOH/CH_3COO^- buffer solution is formed but its pH is about 5 **(c)** yellow; the buffer completely neutralizes the small amount of added OH^- **(d)** red; the buffer capacity is exceeded and the solution becomes basic. **17-4.** Choice **(c)** is the correct one; 0.60 mol $NaCH_3COO$, converts all the HCl to CH_3COOH, producing a $CH_3COOH/NaCH_3COO$ buffer solution of pH $\approx$ 4. Choices **(a)** and **(b)** have essentially no effect on the pH, and while choice **(d)** would neutralize 80% of the acid, the amount of strong acid remaining would still produce a pH $\approx$ 1. **17-5.** This is the titration of a weak base that ionizes in two stages. The titration curve would begin at a moderately high pH; the pH would drop during the titration, and there would be two equivalence points. In general, the curve would resemble that in Figure 17-13, but flipped from bottom to top. The two buffer regions and pH $= pK_b$ values would be in segments of the curve between the two equivalence points. **17-6. (a)** six species: K^+, H_3O^+, I^-,CH_3COO^-, OH^-, CH_3COOH **(b)** most abundant, K^+ (the spectator ion in highest concentration); 2nd most abundant, CH_3COO^- (produced in the neutralization of 3/ 4 of the CH_3COOH) **(c)** least abundant, OH^- (the final solution is acidic, so $[OH^-] < 10^{-7}$ M); 2nd least abundant, H_3O^+ (final solution a buffer with pH $\approx$ 5)

CHAPTER 18

Concept Assessment 18-1. Because of the large excess of $MgF_2(s)$ the solution would remain saturated even when the volume of solution is doubled; $[Mg^{2+}]$ remains constant. **18-2.** CaF_2 and AgCl are insoluble with $K_{sp} = 5.3 \times 10^{-9}$ and $K_{sp} = 1.8 \times 10^{-}10$, respectively. Since K_{sp} values for $CaCl_2$ and AgF are not found in tables, they can be assumed to be soluble compounds. **18-3.** It is largely immaterial. The only requirement is that the $AgNO_3(aq)$ be concentrated enough to bring about the precipitation without unduly diluting the solution from which the precipitation occurs. **18-4.** It will affect the solubility of CaF_2 more. The formation of F^- is derived from the weak acid HF, and so it will undergo hydrolysis whose equilibrium can be changed on the addition of an acid or base. **18-5. (a)** At pH = 10.00, $[OH^-]$=1.0×10^{-4} M and $[Mg^{2+}] = 1.8 \times 10^{-3}$ M, an entirely plausible result. **(b)** At pH = 5.00, $[OH^-] = 1 \times 10^{-9}$ M and $[Mg^{2+}] = 1.8 \times 10^{7}$ M, an impossible result. The situation here is that at pH = 5.00 the solution is not one of $Mg(OH)_2$. It is $MgCl_2(aq)$, and $[Mg^{2+}]$ in this solution depends on the solubility of $MgCl_2$. **18-6.** As expected, with $[Cl^-] = 0.0039$ M, the molar solubility of AgCl(s) is less than in pure water because of the common-ion effect. At higher concentrations of $Cl^-(aq)$, AgCl(s) becomes more soluble because of complex ion formation: $AgCl(s) + Cl^-(aq) \longrightarrow [AgCl_2]^-(aq)$. **18-7.** $Pb^{2+}(aq)$ is present because of the formation of the yellow $PbCrO_4(s)$; $Hg_2{}^{2+}(aq)$ is absent because of the negative test for that ion; the presence of $Ag^+(aq)$ is uncertain because it really wasn't tested for. **18-8.** We must consider the formation of $Pb(OH)_3{}^-$, $K_f = 3.8 \times 10^{14}$, in the solution. **18-9.** Will not work because both ions would precipitate: $(NH_4)_2CO_3$, $H_2S(aq)$, and NaOH(aq); will not work because neither ion would precipitate: $HNO_3(aq)$ and $NH_3(aq)$. HCl(aq) will work because $CuCl_2$ is water soluble and AgCl is not.

CHAPTER 19

Concept Assessment 19-1. No, spontaneous and nonspontaneous refer to the thermodynamics of a process, not the kinetics. A nonspontaneous process will not occur without external intervention, and a spontaneous reaction is not necessarily fast; it can occur very slowly. **19-2.** Doubling the volume available to the gas in Figure 19-1. is equivalent to doubling the length of the box from *L* to 2*L* in Figure 19-3a. The expansion of the gas in Figure 19-1 seems driven by a tendency to fill all the available volume. The gas expansion can also be explained, however, as the tendency of the system energy to be distributed among the greater number of available energy levels in the 2*L* box compared to the *L* box. **19-3.** ΔH as a function of *T* is a straight line with only a slight slope (positive or negative), in the negative energy region. The $T\Delta S$ line, in the same energy region, has a steep negative slope and intersects the ΔH line. The distance between the two lines $(\Delta H - T\,\Delta S)$ represents ΔG. At the point of intersection, $\Delta G = 0$, at *T* below the intersection $\Delta G < 0$, and at *T* above the intersection $\Delta G > 0$. **19-4.** $G° = 326.4\ \text{kJ mol}^{-1}$ means that the Gibbs energy change for the system is 326.4 kJ when 3 mol O_2 is converted into 2 mol O_3. If 1.75 mol O_2 reacts, then the Gibbs energy change for the system is $(326.4\ \text{kJ}/3\ \text{mol}\ O_2) \times (1.75\ \text{mol}\ O_2) = 190.4$ kJ. **19-5.** $H_2O(l, 1\ \text{atm}) \rightleftharpoons H_2O(g, 1\ \text{atm})$, is a process in which $\Delta H > 0$ and $\Delta S > 0$, as represented by Figure 19-9. Below 100 °C, condensation of $H_2O(g, 1\ \text{atm})$ is favored and at 100 °C (the normal boiling point) condensation and vaporization are at equilibrium and $\Delta G = 0$. At 120 °C, vaporization predominates, $\Delta G < 0$, and $T\,\Delta S > \Delta H$.

CHAPTER 20

Concept Assessment 20-1. At the anode, Zn(s) is oxidized to $Zn^{2+}(aq)$ and, to preserve charge balance, $NO_3{}^-(aq)$ migrates in from the salt bridge. At the cathode, $Cu^{2+}(aq)$ is reduced to Cu(s) and, to preserve charge balance, $K^+(aq)$ migrates in from the salt bridge. **20-2.** No changes in mass at the inert Pt(s) electrodes; a gain in mass at the Cu(s) electrode through the half reaction $Cu^{2+}(aq) + 2\,e^- \longrightarrow Cu(s)$; and a loss in mass at the Zn(s) electrode through the half reaction $Zn(s) \longrightarrow Zn^{2+}(aq) + 2\,e^-$. **20-3.** Standard-state conditions for $ClO_4{}^-(aq)$ and $H^+(aq)$ are $a \approx 1$ M; for $Cl_2(g)$, $a = 1$ bar $\approx$ 1 atm; for $H_2O(l)$, $a = 1$. **20-4.** The cell with $E° > 0$ proceeds toward the formation of more products. A net reaction also occurs in the case where $E° < 0$, but in the reverse direction; the concentrations on the left side of the equation increase and those on the right decrease, until equilibrium is reached. **20-5.** $E_{cell} = E°_{cell}$ if all reactants and products are in their standard states, but also for any set of concentrations where $Q = 1$ in equation (20.18). **20-6.** The precipitate is $PbSO_4(s)$, thereby reducing $[Pb^{2+}]$ in the anode compartment and increasing the value of E_{cell}, so that $E_{cell} > E°_{cell}$. **20-7.** The cell diagram $Pt(s)|Cl_2(g, 1\ \text{atm})|Cl^-(0.50\ \text{M})\,||\,Cl^-(0.10\ \text{M})|Cl_2(g, 1\ \text{atm})|Pt(s)$ has the net cell reaction: $0.50\ \text{M}\ Cl^-(aq) \longrightarrow 0.10\ \text{M}\ Cl^-(aq)$ and $E_{cell} = -0.0592\ \text{V} \times \log(0.10/0.50) = 0.041$ V. **20-8.** In a calomel electrode, reduction potential depends on the chloride potential. Therefore, the standard reduction potential for a calomel electrode has a different chloride concentration from the saturated calomel electrode. **20-9.** Dry cells and lead-acid cells "run down" as the concentrations of reactants and products eventually reach their equilibrium values, where ΔG and E_{cell} both become 0. This does not happen in a fuel cell because fuel is continuously added. **20-10.** Both Al and Zn can be used because they are more active than Fe; Ni and Cu are less active and cannot be used.

CHAPTER 21

Concept Assessment 21-1. AlF_3 will have the higher melting point. **21-2.** The Na^+, K^+, Rb^+ and Cs^+ ions have relatively low charge densities and are better able to stabilize large, polyatomic anions such as $NO_2{}^-$. Because the Li^+ ion has a very high charge density and high polarizing power, it may kinetically assist the decomposition of polyatomic anions, such as $N_3{}^-$ and $N_2{}^-$, to smaller anions such as O_2^-. Balanced chemical equations for the reactions are: $MNO_3(s) \xrightarrow{\Delta} MNO_2(s) + {}^1\!/_2\,O_2(g)$ (M = Na, K, Rb, Cs); $2\,LiNO_3(s) \xrightarrow{\Delta} Li_2O(s) + 2\,NO_2(g) + {}^1\!/_2\,O_2(g)$. **21-3.** The hybridization of Be changes from *sp* to sp^2 to sp^3 on going from $BeCl_2$ to $(BeCl_2)_2$ and $(BeCl_2)_n$ and the geometry around the Be atom changes from linear to trigonal planar to tetrahedral. **21-4.** A plausible reaction is that Mg(s) is oxidized to MgO(s) and $CO_2(g)$ is reduced to C(s), that is, $2\,Mg(s) + CO_2(g) \longrightarrow 2\,MgO(s) + C(s)$. **21-5.** For all but beryllium, heating the group 2 carbonates (MCO_3) yields the corresponding oxide (MCO); see equation (21.11). One method for preparing BeO is to burn Be(s) in O_2. **21-6.** The small size of Be^{2+} precludes the possibility of six H_2O molecules coordinating to the central Be^{2+} ion, whereas this happens readily with the Mg^{2+} ion. **21-7.** Lithium and magnesium form ions, Li^+ and Mg^{2+} that have high charge densities and are strongly polarizing. Presumably, when these ions are formed, their charge densities are large enough to stabilize the N^{3-} anion. Balanced chemical equations for the reactions are: $3\,Li(s) + {}^1\!/_2\,N_2(g) \rightarrow Li_3N(s)$; $3\,Mg(s) + N_2(g) \rightarrow Mg_3N_2(s)$. **21-8.** The structure of $B_2H_2(CH_3)_4$ is analogous to diborane (Fig. 21-11a) with two bridging H atoms and four methyl groups ($—CH_3$) in the terminal positions. **21-9.** AlF_3 is an electron-deficient compound and forms $[AlF_4]^-$ in the presence of F^- from KF. BF_3 is a stronger Lewis acid than AlF_3 and abstracts a F^- ion from $[AlF_4]^-$. The result: $[AlF_4]^- + BF_3 \longrightarrow AlF_3(s) + [BF_4]^-$. **21-10.** Determine $\Delta H°$ for each reaction using equation (7.21), the only difference is replacing 1 mol CO_2 in equation (21.29) by 1 mol CO in equation (21.30). The difference in the heat of reaction is -110.5 kJ/mol CO(g) $-$ $[-393.5$ kJ/mol $CO_2(g)] = 283$ kJ. Reaction (21.30) liberates 238 kJ less heat than reaction (21.29). **21-11.** Refer to pages 958 and 959 and imagine a chain of tetrahedra starting with $SiO_4{}^{4-}$ and increasing in increments of $SiO_3{}^{2-}$, yielding $SiO_4{}^{4-}$, $Si_2O_7{}^{6-}$, $Si_3O_{10}{}^{8-}$ $Si_4O_{13}{}^{10-}$, $Si_5O_{16}{}^{12-}$, $Si_6O_{19}{}^{14-}$. Now bend the six-unit silicate chain into a hexagonal ring (similar to that in the third structure on page 958) by eliminating one O^{2-} between the ends of the chain. The result is the anion $Si_6O_{18}{}^{12-}$. In beryl, 3 Be^{2+} and 2 Al^{3+} provide the necessary 12 units of positive charge. **21-12.** Dissolved O_2 (g) in Sn^{2+}(aq) is able to oxidize Sn^{2+} to Sn^{4+}. The following spontaneous reaction reduces tin (IV) to tin (II): $Sn^{4+}(aq) + Sn(s) \longrightarrow 2\,Sn^{2+}(aq)$; $E°_{cell} = 0.154\ V - (-0.137\ V) = 0.017\ V$. Thus, as long as an excess of Sn(s) is present, the Sn^{2+}(aq) can be maintained with little or no Sn^{4+}(aq) present.

CHAPTER 22

Concept Assessment 22-1. The larger EN difference and shorter bond length between Xe and F, compared to Xe and Cl, makes XeF_2 a more stable molecule than $XeCl_2$. **22-2.** The ions do not have the same shape. $ICl_2{}^+$ (VSEPR notation, AX_2E_2) has a tetrahedral electron-group geometry and a bent molecular shape. $ICl_2{}^-$ (VSEPR notation, AX_2E_3) has a trigonal-bipyramidal electron-group geometry, and a linear molecular shape. **22-3.** $CuSO_4$(aq) yields Cu(s) at the Pt cathode and O_2(g) at the Pt anode, and NaI(aq) yields I_2 at the anode and H_2(g) at the cathode. The other three solutions—H_2SO_4(aq), NaOH(aq), and KNO_3(aq)—all yield H_2(g) at the cathode and O_2(g) at the anode. **22-4.** O_3 and $O_3{}^-$ are both V shaped. The Lewis structures for these species suggest that the central O atom is sp^2 hybridized in O_3 and sp^3 hybridized in $O_3{}^-$; thus, the ideal bond angles are 120° for O_3 and 109° in $O_3{}^-$. Experiment shows that the $O—O—O$ bond angles in these two molecular species are much closer: 117° in O_3(g) and 114° in KO_3(*s*). The experimental results suggest that valence bond theory not entirely satisfactory for describing the bonding O_3 and $O_3{}^-$, and a molecular orbital approach is more appropriate. (According to molecular orbital theory, the extra electron in $O_3{}^-$ occupies an antibonding orbital. As a result, the oxygen–oxygen bonds in $O_3{}^-$ are slightly longer than in O_3, but the bond angle is not significantly affected. **22-5.** The Cl in OCl_2 shows more positive character (blue color) than does F in OF_2 because the electronegativity of Cl is considerably less than that of F. **22-6.** The condensed structural formulas for phosphoric acid and phosphorous acid are $OP(OH)_3$ and $HPO(OH)_2$, respectively. **22-7.** The Br atom is larger than the Cl atom. A central P atom can accommodate only four Br atoms, as in the tetrahedral $PBr_4{}^+$ ion. But the central P atom can accommodate either four Cl atoms, as in the tetrahedral $PCl_4{}^+$ ion, or six, as in the octahedral $PCl_6{}^-$ ion.

CHAPTER 23

Concept Assessment 23-1. The electron configuration of Fe is $[Ar]3d^64s^2$ and for Fe^{3+}, $[Ar]3d^5$. The $3d^5$ subshell is half-filled and especially stable. Cobalt ($[Ar]3d^74s^2$) and nickel ($[Ar]3d^84s^2$) must lose four and five electrons, respectively, to achieve a half-filled 3*d* subshell. They simply lose the two 4*s* electrons instead. **23-2.** Both involve reducing metallic compounds to the free metal, often from the same ores. Pyrometallurgy employs high temperatures, yields impure metals that must be refined, and generates gaseous emissions and solid wastes. Hydrometallurgy involves leaching desired metal ions into an aqueous solution, followed by chemical or electrolytic reduction to the metal. Lower temperatures are used, gaseous emissions are largely eliminated, but liquid waste solutions are generated. **23-3.** $Fe_2O_3(s) + 3\,H_2(g) \xrightarrow{\Delta} 2\,Fe(s) + 3\,H_2O(g)$ **23-4.** The $[Cr_3O_{10}]^{2-}$ anion consists of three tetrahedral structures arranged around the backbone $Cr—O—Cr—O—Cr$. The central Cr atom of the backbone is bonded to two additional O atoms and the Cr atoms at the ends to three other O atoms for a total of 10 O atoms. The O. S. of Cr is +6 and that of O is −2 (accounting for the 2− charge on the anion). Similar anions are polysilicate (Fig. 21-31) and polyphosphate (Fig. 22-22). **23-5.** The CO groups in $Fe(CO)_5$ are neutral molecules; the sum of the O.S. of the C and O is 0, and the O.S. of Fe is also 0. **23-6.** Au ($Z = 79$, group 11) has the electron configuration $[Xe]4f^{14}5d^{10}6s^1$; the electrons lost in forming Au^{3+} are the 6s and two of the 5*d*, resulting in $[Xe]4f^{14}5d^8$. **23-7.** The five pairs of electrons around the Cd^{2+} central ion in $[CdCl_5]^{3-}$ is consistent with trigonal bipyramidal molecular geometry (see Table 10-1).

CHAPTER 24

Concept Assessment 24-1. Only one possibility for a six-coordinate complex—$[AlCl_3(H_2O)_3]$—a non-electrolyte that does not conduct electricity and yields no precipitate with $AgNO_3$(aq). Three possible four-coordinate complexes: $[AlCl(H_2O)_3]Cl_2$, $[AlCl_2(H_2O)_2]Cl \cdot H_2O$, and $[AlCl_3(H_2O)] \cdot 2\,H_2O$. The first two of these three can be differentiated by conductivity measurements; the first is the better conductor. The third cannot be distinguished from the six-coordinate complex by Werner's method. **24-2.** Three N atoms can donate an electron pair, so the ligand is tridentate. **24-3.** The formula of the coordination compound is $K_3[FeBr_2Cl_2(OH)_2]$ and the name is potassium dibromodichlorodihydroxoferrate(III). **24-4.** As seen from the models in the margin, substitution of a fourth Cl^- in the *mer*-isomer leads to all four Cl^- ligands in the same plane, but this same isomer cannot be obtained by substituting a fourth Cl^- in the *fac*-isomer. **24-5.** Structures **(a)** and **(d)** are identical and are geometric isomers of **(b)**, **(c)**, and **(e)**. Structures **(e)** and **(c)** are enantiomers, and **(b)** and **(e)** are identical. **24-6 (i)** 4 **(ii)** 3 **(iii)** 5 **(iv)** 2 **(v)** 1 **24-7.** Both ligands form chelates, but $[Cr(EDTA)]^-$ does so in a single step, while $[Cr(en)_3]^{3+}$ requires a succession of three steps. The β_1 for $[Cr(EDTA)]^-$ is much larger than β_1 or β_2 of $[Cr(en)_3]^{3+}$, but the cumulative formation constant, β_3 (or K_f), of $[Cr(en)_3]^{3+}$ should be similar to β_1 (or K_f) of $[Cr(EDTA)]^-$.

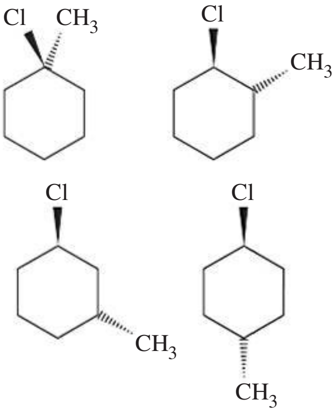
CHAPTER 25

Concept Assessment 25-1. Radioactive decay that changes *Z* produces a different element. This includes α, β^-, β^+ emissions and electron capture. If there is no change in *Z* (emission of γ rays) the element remains the same. **25-2.** Francium, a radioactive element, is produced in the decay schemes of heavier elements and found only in conjunction with other decay products, not in natural sources of the alkali metals that Fr resembles. **25-3.** Radioactive nuclides with very long half-lives have a very low activity; those with very short half-lives have a high activity but they do not persist long. Those with intermediate half-lives may persist in the environment for a significant period of time at a high activity, making them potentially the most hazardous. **25-4.** Refer to Table 25.2 and Figure 25-7 and focus on magic numbers and the relative thickness and width of the belt of stability for a fixed proton number and a fixed neutron number. The greatest thickness comes at the magic number, $Z = 50$. (Tin has 10 stable isotopes.) The greatest width comes at the magic number, $N = 82$. (There are 7 stable nuclides with 82 n.) **25-5.** Refer to Figure 25-7. The point representing ^{44}Ca falls in the belt of stability; ^{44}Ca is a stable nuclide. ^{57}Cu falls below the $N = Z$ line and in the region of β^+ emission, while ^{100}Zr falls above the belt of stability and decays by β^- emission. ^{235}U falls above and beyond the belt of stability and decays by α-particle emission.

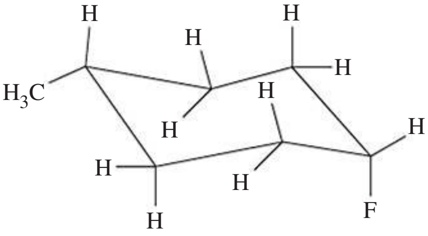
CHAPTER 26

Concept Assessment 26-1. All structures based on F atoms at two of the vertices of a tetrahedron and H atoms at the remaining two are superimposable. Only one molecule has the formula CH_2F_2. Two possibilities exist for four atoms at the corners of a square—two F atoms on one side (cis) or on opposite corners (*trans*). **26-2.** No. A quaternary carbon atom is bonded to four other carbon atoms.

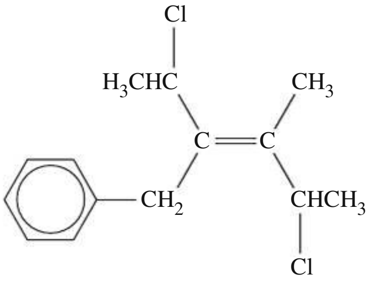
26-3. 2-pentanol. **26-4.** The generic formula of an alkane is C_nH_{2n+2}, and for an alkyl halide where an X atom replaces one H atom, $C_nH_{2n+1}X$. If we limit the series to straight-chain alkanes with X as a terminal atom, we have $H(CH_2)_nX$. That is, $n = 1$, HCH_2X or CH_3X; $n = 2$, HCH_2CH_2X or CH_3CH_2X; $n = 3$, $HCH_2CH_2CH_2X$ or $CH_3CH_2CH_2X$; and so on. **26-5.** Yes. **26-6.**



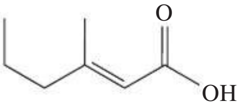
26-7. The conformer with the methyl group in the axial position has higher energy, and so it would release more energy, as heat, if burned. **26-8.** The lower energy conformation is:



The larger group, $-CH_3$, is in the equatorial position. **26-9.** There are two chiral centers, at the 2nd and 3rd C atoms (to which Br atoms are attached), and four stereoisomers. To show this, sketch a dashed line-wedge structure with the two Br atoms on the same side of the molecule; next to it sketch its nonsuperimposable mirror image. Sketch another structure with the two Br atoms on opposite sides of the molecule and its mirror image, making a total of four stereoisomers. **26-10.**



26-11. In butyl acohol —OH attaches to either of the indicated C atoms in the skeleton C—C*—C*—C; in both cases the molecule is the same and there is only one *s*-butyl alcohol. In pentyl alcohol, —OH attaches to one of the indicated C atoms in C—C*—C#—C*—C. Here, the two structures are the same if attachment is at a C* atom, but a different molecule results if attachment is to the C# atom. The name "s-pentyl alcohol" is inadequate. **26-12.**



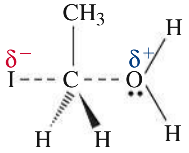
26-13. No, because $C_3H_6O_2$ has only one element of unsaturation. A dialdehyde has two π bonds, and thus two elements of unsaturation.

CHAPTER 27

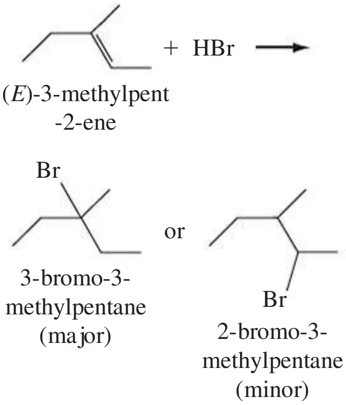
27-1. CH_3CN is aprotic; NH_3 is protic; $(CH_3)_3N$ is aprotic; $HCONH_2$ is protic; CH_3COCH_3 is aprotic. **27-2.** The minor product is the substitution product, $(CH_3)_3C—OCH_2CH_3$, an ether.

Because the substrate is a 3° haloalkane (which disfavors backside attack) and the solvent is polar protic (and stabilizes a carbocation), the ether is formed by the S_N1 mechanism.

27-3.



27-4.

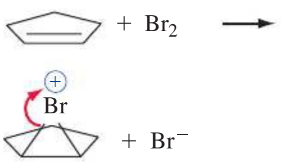


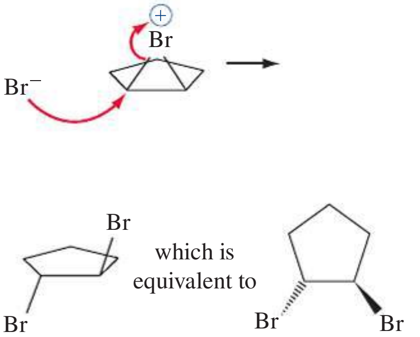
(*E*)-3-methylpent-2-ene

3-bromo-3-methylpentane (major)

2-bromo-3-methylpentane (minor)

27-5. A mixture of enantiomers would be obtained because hydration proceeds through a carbocation. The carbocation can be attacked from above or below by a water molecule, and so both the (*R*) and (*S*) configurations of 2-butanol will be produced. **27-6.** The product will be *trans*-1,2-dibromocyclopentane. If the bromonium ion is formed with the Br atom situated above the plane of the ring, then Br^- will attack from below the plane of the ring because it must attack from the backside. Therefore, the *trans* isomer is obtained:





trans isomer .

27-7. Once formed, CH_3Cl can react with a Cl to form a $H_2ClC\cdot$ radical. A $H_2ClC\cdot$ radical can then react with a $H_3C\cdot$ radical to form $ClCH_2CH_3$. **27-8.** $(CH_3)_2CBrCH_2CH_3$.

CHAPTER 28

Concept Assessment 28-1. The products are 1 mol glycerol and 1 mol each of sodium palmitate, sodium oleate, and sodium linoleate. **28-2.** The mirror image of a (+) enantiomer is the (−) enantiomer, so the mirror image of D-(+)-glucose is L-(−)-glucose. There can be no D-(−)-glucose. **28-3.** This polypeptide structure is shown in Example 28-1. Ionization occurs only at the N-terminal and C-terminal ends of the chain and nowhere else along the chain. Since the N-terminal and C-terminal amino acids are at a pH more than one unit above their isoelectric points, the only significant ionization is at the C-terminal amino acid, which would be present as a 1− anion, making the net charge on the tripeptide also 1−. **28-4.** Helix formation in a protein (Fig. 28-12) requires close proximity of carbonyl and amide groups and formation of hydrogen bonds between them, occurring regularly over an entire macromolecule. In the polysaccharides (Fig. 28-9), O atoms and —OH groups could conceivably form hydrogen bonds between them, but more randomly and not in the very tight helical fashion seen in proteins.

CHAPTER 1 **p. 1,** Science VU/NASA/ESA/Visuals Unlimited, Inc.; **p. 3,** Stamp from the private collection of Professor C. M. Lang. Photography by Gary J. Shulfer, University of Wisconsin, Stevens Point. "1973, France (Scott #B468)"; Scott Standard Postage Stamp Catalogue, Scott Pub. Co., Sidney, Ohio; **p. 4,** Paul Silverman/Fundamental Photographs, Inc.; **p. 5, 1.3,** Diane Schiumo/Fundamental Photographs, Inc.; **p. 6,** Eye of Science/Science Photo Library; **p. 7, 1-5a/b** Carey B. Van Loon; **1-5c/d,** Richard Megna/Fundamental Photographs, NYC; **1-6,** Carey B. Van Loon; **p. 8, 1-7,** Mehau Kulyk/Science Photo Library; **p. 10,** Richard Megna/Fundamental Photographs, NYC; **p. 16, 1-10 (both),** Kristen Brochmann/ Fundamental Photographs, NYC; **bottom,** Richard Megna/Fundamental Photographs, NYC; **p. 19 (left and right),** Richard Megna/Fundamental Photographs, NYC; **p. 21, 1-12,** Carey B. Van Loon; **p. 32 (92)**, Sargent-Welch/VWR International, **p. 32 (93),** Tom Leininger/University of Kansas School of Engineering

CHAPTER 2 **p. 34,** Courtesy of the Oak Ridge National Laboratory, managed by the U.S. Department of Energy by UT-Battelle, LLC; **p. 35, 2-1,** Carey B. Van Loon; **2-2a/b,** Richard Megna/Fundamental Photographs, NYC; **p. 36 (a),** Katrina Brown/Dreamstime.com, **(b),** Photos.com/Jupiterimages Unlimited; **p. 38,** Sheila Terry/Science Photo Library; **p. 39, 2-4a,** Fundamental Photographs, NYC; **p. 55, 2-17,** Carey B. Van Loon; **p. 56, 2-18,** Richard Megna/Fundamental Photographs, NYC

CHAPTER 3 **p. 68,** Dr. Jeremy Burgess/Science Photo Library; **p. 70, 3-1 (left),** Carey B. Van Loon; **p. 86, 3-7,** Carey B. Van Loon; **p. 93, 3-8,** Tom Pantages; **p. 109,** Carey B. Van Loon

CHAPTER 4 **p. 111,** Roger Ressmeyer/Terra/Corbis; **p. 112, 4-1,** Richard Megna/Fundamental Photographs, NYC; **4-2a,** Richard Megna/Fundamental Photographs, NYC; **4-2b,** Tom Bochsler/Pearson Education/PH College; **p. 125, 4-5a/b/c,** Richard Megna/Fundamental Photographs, NYC; **p. 127, 4-7a/b/c,** Richard Megna/Fundamental Photographs, NYC; **p. 149 (left),** Ed Degginger/Color-Pic, Inc.; **(right),** Robert Mathena/Fundamental Photographs, Inc.

CHAPTER 5 **p. 151,** Richard Megna/Fundamental Photographs, NYC; **p. 152, 5-1a,** Tom Pantages; **5-1b,** C Squared Studios/Photodisc/Getty Images; **p. 154, 5-4a/b/c,** Richard Megna/Fundamental Photographs, NYC; **p. 157, 5-6,** Richard Megna/Fundamental Photographs, NYC; **5-7a/b/c,** Richard Megna/Fundamental Photographs, NYC; **p. 158, 5-8,** Carey B. Van Loon; **p. 161, 5-9,** Carey B. Van Loon; **p. 164, 5-10,** Nicola Keegan/iStockphoto.com; **p. 166, 5-11,** Tom Pantages; **p. 167, 5-12a/b/c,** Joel Gordon; **p. 169, 5-13,** Carey B. Van Loon; **p. 174, 5-14,** Phil Degginger/Color-Pic, Inc.; **p. 176, 5-16,** Kristen Brochmann/Fundamental Photographs, NYC; **p. 178, 5-17a/b/c,** Carey B. Van Loon; **p. 180, 5-18a/b/c,** Carey B. Van Loon; **p. 182,** Carey B. Van Loon; **p. 187 (a&b),** William H. Breazeale/Francis Marion University; **(c),** Tom Pantages

CHAPTER 6 **p. 192,** Carlos Caetano/Shutterstock; **p. 193, 6-1,** Carey B. Van Loon; **6-2,** Kristen Brochmann/Fundamental Photographs, NYC; **p. 194, 6-3,** Richard Megna/Fundamental Photographs, NYC; **p. 201,** Science Source/Photo Researchers, Inc.; **p. 202,** Stamp from the private collection of Professor C. M. Lang. Photography by Gary J. Shulfer, University of Wisconsin, Stevens Point. "1956, Italy (Scott #714)"; Scott Standard Postage Stamp Catalogue, Scott Pub. Co., Sidney, Ohio; **p. 203, 6-9,** Carey B. Van Loon; **p. 210, 6-11,** Carey B. Van Loon; **p. 223, 6-18,** Richard Megna/Fundamental Photographs, NYC; **p. 232 (both)** Richard Megna/Fundamental Photographs, NYC

CHAPTER 7 **p. 241,** Richard Megna/Fundamental Photographs, NYC; **p. 242, 7-1,** Kristen Brochmann/Fundamental Photographs, NYC; **p. 243, 7-2,** Richard Megna/ Fundamental Photographs, NYC; **p. 244,** Science Photo Library; **p. 249 (a&b),** Carey B. Van Loon; **p. 268,** Tom Pantages; **p. 269,** Carey B. Van Loon; **p. 278,** Simon Fraser/Science Photo Library

CHAPTER 8 **p. 294,** Dennis Kunkel Microscopy, Inc./Visuals Unlimited, Inc.; **p. 298, 8-4a,** Richard Megna/Fundamental Photographs, NYC; **8-4b,** Douglas Freer/iStockphoto.com; **p. 299, 8-6,** Richard Megna/Fundamental Photographs, NYC; **p. 300, 8-7a,** Theo Gottwald/Dreamstime.com; **8-7b,** Photos.com/Jupiterimages Unlimited; **8-8a,** Carey B. Van Loon; **8-8b/c/d/e,** Tom Pantages; **p. 301, 8-9 (left),** Richard Megna/Fundamental Photographs, NYC; **8-9 (right),** Wabash Instrument Corp./Fundamental Photographs, NYC; **8-10,** Wabash Instrument Corp./Fundamental Photographs, NYC; **p. 302,** Oleg Fedorenko/iStockphoto.com; **p. 303,** AIP Emilio Segre Visual Archives, gift of Jost Lemmerich; **p. 305,** Bettmann/Corbis; **p. 307,** Stamp from the private collection of Professor C. M. Lang. Photography by Gary J. Shulfer, University of Wisconsin, Stevens Point. "1963, Denmark (Scott #409)"; Scott Standard Postage Stamp Catalogue, Scott Pub. Co., Sidney, Ohio; **p. 313,** The Nobel Foundation; **p. 314, 8-16a/b,** Courtesy of The Education Development Center; **p. 315,** Photograph by Paul Ehrenfest, Jr., courtesy AIP Emilio Segre Visual Archives, Weisskopf Collection

CHAPTER 9 **p. 360,** IBM Research, Almaden Research Center; **p. 362,** Stamp from the private collection of Professor C. M. Lang. Photography by Gary J. Shulfer, University of Wisconsin, Stevens Point. "1957, Russia (Scott #1906) and 1969, Russia (Scott #3607)"; Scott Standard Postage Stamp Catalogue, Scott Pub. Co., Sidney, Ohio; **p. 363,** Bettmann/Corbis; **p. 364, 9-2b,** British Department of the Environment, Transport and the Regions; **p. 382, 9-13,** Carey B. Van Loon; **p. 384, 9-15a,** Ed Degginger/Color-Pic, Inc.; **9-15b,** Carey B. Van Loon; **9-16,** Carey B. Van Loon; **p. 385, 9-17a/b,** Carey B. Van Loon

CHAPTER 10 **p. 396,** UPI/Bettmannn/Corbis; **p. 401, 10-3,** Richard Megna/Fundamental Photographs, NYC; **p. 424, 10-12,** Carey B. Van Loon; **p. 425, Table 10.1 (all),** Carey B. Van Loon; **p. 426, Table 10.1**, Carey B. Van Loon

CHAPTER 11 **p. 453, 11-5,** Carey B. Van Loon; **p. 455, 11-9,** Carey B. Van Loon; **p. 456, 11-10,** Carey B. Van Loon; **p. 458, 11-12a/b,** Carey B. Van Loon; **p. 462, 11-15,** Carey B. Van Loon; **p. 474,** UPI/Bettmann/Corbis; **p. 476, 11-31,** Clive Freeman, The Royal Institution/Science Photo Library

CHAPTER 12 **p. 498,** Brytta/iStockphoto.com; **p. 499, 12-1,** Tom Pantages; **p. 500, 12-3a/b,** Carey B. Van Loon; **p. 504, 12-8,** Richard Megna/Fundamental Photographs, NYC; **p. 505,** Uros Medved/Dreamstime.com; **p. 508, 12-10,** Carey B. Van Loon; **p. 509, 12-12,** Carey B. Van Loon; **12-13,** Ed Degginger/Color-Pic, Inc.; **12-14;** Carey B. Van Loon; **p. 510, 12-15,** Tom Pantages; **p. 517, 12-21 (both),** Carey B. Van Loon; **p. 518,** Richard Megna/Fundamental Photographs, NYC; **12-22 (all),** Images of critical point of benzene taken from Chemistry Comes Alive! By Jerrold J. Jacobsen, John W. Moore, et al., published by Journal of Chemical Education Software; **p. 521, 12-25,** Carey B. Van Loon; **p. 523,** Richard Megna/Fundamental Photographs, NYC; **p. 527,** Tom Pantages; **p. 528, 12-34d,** Tom Pantages; **12-35b,** Boris I. Yakobson and Richard E. Smalley, Rice University; **p. 531, 12-38 (all),** Richard Megna/Fundamental Photographs, NYC; **(bottom),** Adalberto Rios Szalay/Sexto Sol/Photodisc/Getty Images; **p. 532, 12-39a (right, both),** Carey B. Van Loon; **p. 533, 12-40 (both),** Carey B. Van Loon

CHAPTER 13 **p. 557,** Richard Megna/Fundamental Photographs, NYC; **p. 569, 13-9,** Richard Megna/Fundamental Photographs, NYC; **p. 571, 13-10,** Carey B. Van Loon; **(bottom),** Charles D. Winters/Photo Researchers, Inc.; **p. 572,** Kevin Panizza/Dreamstime.com; **p. 576,** winhorse/iStockphoto.com; **p. 577, 13-16b,** Richard Megna/Fundamental Photographs, NYC; **p. 580 (all),** Dr. David Phillips/Visuals Unlimited, Inc.;

  - used in molarity, 124
- volume factor, 227
- volume percent, 558–559
- VSEPR theory. *See* valence-shell electron-pair repulsion (VSEPR)
- vulcanization, 1251

W

- water
  - addition reaction, 1241–1242
  - Avogadro's hypothesis, 202*f*
  - boiling, 517
  - boiling point, 850

water *(cont.)*
  bonding, 455
  calcium, reaction with, 383–384, 384*f*
  chlorine water, 992
  composition of, 36–37
  cooling curve, 519–521, 520*f*
  electrostatic potential map, 431*f*
  formation of water, 202*f*
  freezing of water, 832–833
  frozen. *See* ice
  gas collected over water, 215–216
  gaseous water, 8*f*
  heating curve, 521, 521*f*
  at high combustion temperature, 115
  hydrated, 566
  hydrogen bonding in, 503–504, 503*f*
  ice. *See* ice
  ion product of water, 704
  liquid water, 8*f*, 504
  moisture detector, 93
  molecular mass, 73
  molecular view, 152*f*
  molecule of, 5
  monolayer, 109
  ordinary water, 4
  phase diagram, 524, 524*f*
  polar molecules, 431
  potassium, reaction with, 241*f*, 383–384, 384*f*
  present in compounds, 93
  pure water. *See* pure water
  qualitative test for chlorine in tap water, 157*f*
  seawater. *See* seawater
  self-ionization, 703–706, 792, 943
  separating mixtures, 7*f*
  solution. *See* aqueous solution
  specific heat, 247
  states of water, 8, 8*f*
  supercooled droplets, 838
  vapor pressure, 513*t*
  vaporization of water, 838
  waves, 295
  wetting of a surface, 508–509, 509*f*
water gas, 1018
water-gas shift reaction, 672
water of crystallization, 924
water solution. *See* aqueous solution
water vapor, 82, 215, 577*f*, 578
water vapor pressure, at various temperatures, 215*t*
